* Supporting Information

ABSTRACT: We combine infrared and Raman spectroscopies to investigate finite length scale effects in CuGeO₃ nanorods. The infrared-active phonons display remarkably strong size dependence whereas the Raman-active features are, by comparison, nearly rigid. A splitting analysis of the Davydov pairs reveals complex changes in chemical bonding with rod length and temperature. Near the spin-Peierls transition, stronger intralayer bonding in the smallest rods indicates a more rigid lattice which helps to suppress the spin-Peierls transition. Taken together, these findings advance the understanding of size effects and collective phase transitions in low-dimensional oxides.

KEYWORDS: Spin-Peierls transition, magnetoelectric coupling, size effects, phonon confinement, nanorods, vibrational spectroscopy

Phase transitions in nanomaterials are a subject of contemporary interest. This is because of the remarkable mechanistic diversity in how size enables the development of new states of matter,1,2 disrupts one transition in favor of another,3,4 or blocks the development of collective phenomena entirely.5,6 One example of a transition with emergent properties is that of oxides such as BiFeO₃, where the nanoparticles display a ferroelectric → paraelectric crossover with decreasing size.7 The development of the super-paramagnetic state in CoFe₂O₄ and MgFe₂O₄ nanoparticles is another illustration of how size allows access to completely different properties and areas of phase space.8,9 Other examples include the spin-flop transition in α-Fe₂O₃ that is suppressed below approximately 8 nm10,11 and magnetoelectric coupling in Fe₂O₃ which is reduced with decreasing size.12 The discovery of size-induced quenching of the spin-Peierls transition in nanoscale CuGeO₃,13,14 is another case where collective phenomena are suppressed by length scale effects. That the spin-Peierls state can be switched with both temperature and size is intriguing and merits additional mechanistic investigation.

CuGeO₃ is well-known as the first inorganic spin-Peierls material15 and, as such, is a superb platform for exploring temperature,16−19 magnetic field,20−23 pressure,24−26 and doping effects.27−33 This system consists of edge-sharing CuO₆ octahedra that form quasi-one-dimensional chains along the crystallographic c-axis (Figure 1a).18,34 The Cu centers are d² and therefore S = 1/2. The Cu atoms dimerize below the Tₛₚ = 14 K spin-Peierls transition,15 and spin gaps open because singlets are formed.15,35 Vibrational spectroscopies reveal the coupled phonons.18,36−40 The recent development of a suite of CuGeO₃ nanorods of different lengths13,14 (Figure 1b−d) offers the opportunity to unravel size effects on the dynamic properties and at the same time explore how and why the spin-Peierls transition is suppressed below a critical size (dₕ = 450 nm).13,14 Electron spin resonance reveals no sign of an antiferromagnetic state at small sizes,14 contrary to expectations based upon chemical substitution with Si, Zn, and Mg.41−43 Instead, disorder emanating from the small surface layer and local changes in the Cu−O−Cu superexchange pathway that increase interchain interactions may place CuGeO₃ nanorods in the vicinity of a disorder-driven quantum critical point.14

In this work, we reach beyond temperature, magnetic field, and pressure tuning techniques to explore the vibrational properties of CuGeO₃ nanorods as a function of size. An additional and rather novel aspect of our approach is that while
all nanorod diameters are similar, the growth habit is such that length can be controlled to vary confinement in the c direction (Figures 1b−d). Strikingly, the infrared-active modes show dramatic size effects whereas the Raman-active features are nearly rigid. A Davydov splitting analysis reveals an overall higher intra- to interlayer bonding ratio in the nanorods as compared to the bulk, likely due to enhancement of bc-plane dimensionality. Importantly, at temperatures near the spin-Peierls transition, the intralayer bonding goes through a weak minimum near dcrit and then turns sharply upward with decreasing size. This indicates a lattice that is stiffer and more difficult to dimerize, consistent with the suppression of the spin-Peierls transition at small sizes. Taken together, these findings advance the understanding of size-driven phase transitions in nanoscale transition metal oxides and place these materials on a firm foundation for future work in high magnetic field. Phonon size effects may also be important for catalysis, thermal conductivity, and sensing applications.

Size-Dependent Vibrational Properties of CuGeO3 Nanorods. Figure 2 displays the infrared and Raman scattering response of CuGeO3 as a function of size at 300 K. The spectral features are in reasonable agreement with prior single crystal measurements, so we adopt earlier mode assignments and displacement patterns to describe the lattice dynamics of the nanorods. Within this framework, features below 250 cm−1 are related to copper and germanium motion whereas those above 250 cm−1 contain mostly oxygen displacement. Only a few phonons are important to the 14 K spin-Peierls transition in the single crystal. These include the infrared-active B3u mode near 295 cm−1, an infrared-active folded zone-boundary mode near 800 cm−1, and the Raman-active B3g and B2g modes at 110 and 222 cm−1, respectively. Our initial expectation was that this short list of coupled phonon modes would display signatures of important size-induced changes to the lattice. For example, mode disappearance, splitting, or sudden frequency shifts across the 450 nm critical length scale could indicate the inability of the lattice to dimerize at low temperatures. Upon examination, however, these modes do not seem to be of particular importance to the size-induced suppression of the spin-Peierls transition. The actual situation is more subtle and requires close analysis, as detailed below.

Figure 3 displays frequency versus size trends for several representative infrared-active modes at different temperatures above and below TSP. A full accounting of the infrared features is available in Figure S3. Overall, phonons corresponding to Cu and Ge motions (below 250 cm−1) display weak frequency shifts with decreasing size (Figure 3a−c), whereas those involving oxygen motion exhibit much stronger changes (Figure 3d−f). We distinguish two different types of size effects: (i) a sharp frequency jump going from polycrystal to nanorod that represents confinement perpendicular to the length of the nanorod and (ii) the frequency shift as nanorod length decreases, which correlates to changes along the c-axis. These trends are discussed below.
We first examine $ab$ plane size effects. We do this by realizing that the growth habit of the CuGeO$_3$ nanorods is such that the diameter is always $\approx 50$ nm, within the range of phonon confinement for some oxides.\textsuperscript{47,48} Differences in the infrared response of the polycrystal and largest nanorod sample (which is longer than 1000 nm) can therefore be attributed to finite length scale effects within the $ab$ plane. As expected, phonons polarized along these directions display sizable frequency shifts (up to 55 cm$^{-1}$, see Figure S3), although these shifts occur in different directions (Figure 3d,e, for example). In general, modes polarized along $a$ ($B_{1u}$) soften across the bulk to 1000 nm nanorod size range, whereas $b$-directed ($B_{3u}$) phonons harden. The latter is consistent with overall stronger interchain interactions in the nanorods. Interestingly, the $c$-polarized ($B_{2u}$) modes are also sensitive to this two-dimensional confinement and soften (Figure 3f), even though the length of the longest

![Figure 3. Frequency versus size at 300 K (red), 20 K (green), and 4.2 K (blue) for representative infrared modes of CuGeO$_3$ with the indicated symmetries as approximated from single crystal studies.\textsuperscript{45} (a–c) Modes below 250 cm$^{-1}$ show only a weak size-dependence whereas (d–f) the higher frequency modes display larger frequency shifts. Here, we use infinite size to indicate the polycrystalline bulk material. The vertical shaded region represents the critical length scale $d_{\text{crit}}$ for suppression of the low-temperature spin-Peierls transition. Dashed lines guide the eye.]

![Figure 4. (a–f) Frequency versus size at 300 K (red), 20 K (green), and 4.2 K (blue) for representative Raman modes of CuGeO$_3$ with the indicated symmetries as approximated from single crystal studies.\textsuperscript{45} Note that the frequency scales on the y-axes are much smaller than those in Figure 3 in order to visualize the smaller frequency shifts. The vertical shaded region represents the critical length scale $d_{\text{crit}}$ for suppression of the low temperature spin-Peierls transition. Dashed lines guide the eye.]

We first examine $ab$ plane size effects. We do this by realizing that the growth habit of the CuGeO$_3$ nanorods is such that the diameter is always $\approx 50$ nm, within the range of phonon confinement for some oxides.\textsuperscript{47,48} Differences in the infrared response of the polycrystal and largest nanorod sample (which is longer than 1000 nm) can therefore be attributed to finite length scale effects within the $ab$ plane. As expected, phonons polarized along these directions display sizable frequency shifts (up to 55 cm$^{-1}$, see Figure S3), although these shifts occur in different directions (Figure 3d,e, for example). In general, modes polarized along $a$ ($B_{1u}$) soften across the bulk to 1000 nm nanorod size range, whereas $b$-directed ($B_{3u}$) phonons harden. The latter is consistent with overall stronger interchain interactions in the nanorods. Interestingly, the $c$-polarized ($B_{2u}$) modes are also sensitive to this two-dimensional confinement and soften (Figure 3f), even though the length of the longest
nanorods (along the c-axis) is well above the length scale where finite size effects strongly affect phonon energies.\textsuperscript{7,47,49} We now turn our attention to the infrared response of CuGeO\textsubscript{3} as a function of size. Here, plots of frequency versus size characterize trends that develop as a function of the nanorod length (along the c-axis) while keeping diameter fixed.\textsuperscript{13} One might anticipate that reducing nanorod length will affect only c-directed modes. As shown in Figure 3, this is clearly not the case. There are, however, consistent directional trends. For instance, both a- and b-polarized modes red shift with decreasing size, while the c-polarized (B\textsubscript{3u}) modes harden. The overall spectral character is similar above and below d\textsubscript{crit} with the frequency shifts of interest occurring across 450 nm. Remarkably, the lattice is sensitive to this critical length scale even at room temperature.

Figure 4 displays frequency versus size for several representative Raman features at different temperatures. The size dependence of the Raman-active modes in nanoscale CuGeO\textsubscript{3} is considerably weaker than that of the infrared-active phonons. Most modes display only small frequency shifts regardless of symmetry. This is true both for the jump from polycrystal to longest nanorod (a maximum of 1 cm\textsuperscript{-1} for Raman modes compared to 55 cm\textsuperscript{-1} in the infrared) and the dependence on nanorod length (as high as 11 cm\textsuperscript{-1} for the 116 cm\textsuperscript{-1} Raman mode versus 20 cm\textsuperscript{-1} for the 772 cm\textsuperscript{-1} infrared mode). There are no consistent hardening or softening trends within a particular symmetry. As in the infrared features, most modes begin to display confinement effects below d\textsubscript{crit} ≈ 450 nm, even though the changes are not so large, whereas others are entirely rigid across this size regime. Again, modes harden at low temperature, although the overall shifts are smaller than those of the infrared phonons.

**Evaluating Intra- versus Interlayer Bonding Strength.**

Infrared phonons are exquisitely sensitive to charge and bonding because they directly probe charge on the potential surface.\textsuperscript{50,51} One way to quantify this effect, assuming size-induced changes to the structure and stoichiometry can be ruled out as was done here, is by evaluating chemical bond strength. In materials with multiple formula units per unit cell, this is accomplished with an analysis of the Davydov splitting that arises from the interaction of neighboring formula units.\textsuperscript{45,46,53,54} In our case, the unit cell of CuGeO\textsubscript{3} contains two formula units\textsuperscript{37} which splits the 218, 330, 403, 605, 716, and 851 cm\textsuperscript{-1} modes into Davydov pairs (Figure 5a, for example).\textsuperscript{55} Each pair consists of independent infrared and Raman branches that are split from a central unperturbed frequency. Comparing the frequencies of the infrared and Raman components of the Davydov pairs allows for an analysis of the relative strength of intra- versus interlayer bonding.\textsuperscript{35} We employ this framework to evaluate bonding strength trends in this suite of nanorods.

We observe the majority of known Davydov pairs\textsuperscript{35} in the CuGeO\textsubscript{3} nanorods, supporting a comprehensive analysis of the mode splittings to reveal size-induced changes in bonding. The infrared and Raman branch frequencies (for each pair) are defined as \( \omega_i \) and \( \omega_r \), respectively. We then calculate \( (\omega_i - \omega_r)/\Delta \), which represents the ratio of intralayer to interlayer bonding strength from the relation \( \omega = (\omega_0^2 \pm \Delta^2)^{1/2} \) which is valid for a pair of weakly coupled identical oscillators.\textsuperscript{46,54,55} Here, \( \omega_0 \) is the isolated (unperturbed) oscillator frequency, and \( \Delta \) is proportional to the coupling force constant.\textsuperscript{46,54,55} Tables 1 and 2 summarize this analysis for the doublets centered at 716 and 851 cm\textsuperscript{-1}. As a reminder, these modes are assigned as oxygen stretching around Ge and Cu, respectively.\textsuperscript{30,45}

\( \Delta \) is proportional to the weak coupling between interacting identical oscillators, and \( (\omega_i/\Delta)^2 \) is proportional to the intra-versus-interlayer bonding strength.

[Table 1]

[Figure 5](#Figure5) displays frequency versus size for several representative Davydov doublets in the longest nanorods at 300 K, \( (\omega_i/\Delta)^2 \) versus size as determined from the (a) 716 and (c) 851 cm\textsuperscript{-1} pairs. (d) Averaging over all Davydov pairs yields \( (\omega_i/\Delta)^2 \) versus size, representing the size dependence of intra- versus interlayer bonding strength for CuGeO\textsubscript{3} at 300 (red), 20 (green), and 4.2 K (blue). The vertical shaded region represents the critical length scale \( d_{crit} \) below which the spin-Peierls transition is quenched. Dashed lines guide the eye.

**Figure 5.** (a) Close-up views of the infrared (red) and Raman (blue) spectra of representative Davydov doublets in the longest nanorods at 300 K, \( (\omega_i/\Delta)^2 \) versus size as determined from the (b) 716 and (c) 851 cm\textsuperscript{-1} pairs. (d) Averaging over all Davydov pairs yields \( (\omega_i/\Delta)^2 \) versus size, representing the size dependence of intra- versus interlayer bonding strength for CuGeO\textsubscript{3} at 300 (red), 20 (green), and 4.2 K (blue). [Figure 5](#Figure5)
are reasonable based on unit cell parameter trends in single crystals.\textsuperscript{18} $b$ decreases, $c$ increases, and $d$ is nearly constant with decreasing temperature. Thermal effects are much stronger in the nanorods, an indication that traditional contraction effects are amplified, possibly due to enhanced interchain interactions.

Looking at the 300 K data, we observe strong size effects on $(\alpha_{0}/\Delta)^{2}_{\text{avg}}$ (Figure 5d). With decreasing rod length, $(\alpha_{0}/\Delta)^{2}_{\text{avg}}$ reaches a maximum at $d_{\text{crit}}$ then decreases, indicating that the lattice is sensitive to this critical length scale even far away from $T_{\text{SP}}$ and the onset of magnetic ordering. Because the interlayer bonds are along $a$ and the nanorod length (which varies) is along $c$,\textsuperscript{13} we surmise that the main driver of modifications to $(\alpha_{0}/\Delta)^{2}_{\text{avg}}$ arises from changes in intralayer ($bc$-plane) bonding at small sizes. This change in bonding strength explains the large frequency shifts of infrared modes as compared to Raman analogs. Interestingly, the size-dependent trend at low temperature is quite different from that at 300 K. Instead of reaching a maximum, $(\alpha_{0}/\Delta)^{2}_{\text{avg}}$ goes through a weak minimum near $d_{\text{crit}}$ and sharply rises at smaller sizes. Similar trends are observed at both 20 and 4.2 K. This indicates that the intralayer bonding strengthens at small sizes, which may be responsible for the suppression of the spin-Peierls transition.

**Mechanism of the Size-Induced Quenching of the Spin-Peierls Transition.** The spin-Peierls transition is a cooperative distortion that arises when a quasi-one-dimensional spin chain interacts with surrounding phonons.\textsuperscript{56} When it is blocked (as in the shortest nanorods of interest here), both the spin and lattice channels must be examined to determine the suppression mechanism. The microscopic nature of the coupling phonons in CuGeO$_3$ is well-known,\textsuperscript{18,36–40} providing candidates with which to explore the role of the lattice. With the exception of the 800 cm$^{-1}$ folded zone-boundary phonon, these features appear in our spectra. While there are no dramatic changes such as mode disappearance or splitting near 450 nm, the large frequency shifts below this length scale seem to signal important changes in chemical bonding and dimensionality.

As discussed above, $(\alpha_{0}/\Delta)^{2}_{\text{avg}}$ from the complete Davydov analysis provides a framework within which we can compare overall chemical bonding trends in this set of materials. Figure 5d shows that $(\alpha_{0}/\Delta)^{2}_{\text{avg}}$ is everywhere higher in the nanorods as compared to the polycrystal. This means that intralayer bonding is stronger - regardless of nanorod length. Such increased stiffness makes it more difficult to dimerize the Cu centers, weakening the spin-Peierls transition in the longer nanorods.\textsuperscript{13} In other words, at smaller size scales the intralayer bonding is stronger than the interlayer bonding, leading to an energetic barrier to the dimerization process typically required for a spin-Peierls transition. At low temperature, $(\alpha_{0}/\Delta)_{\text{avg}}$ rises sharply below $d_{\text{crit}}$. This further increase in rigidity works to increase interchain interactions and block the spin-Peierls transition below $d_{\text{crit}}\approx 450$ nm. External stimuli such as strain may have similar effects on stiffness and dimerization and should be explored for property control.

In summary, we measured the spectroscopic response of nanoscale CuGeO$_3$ in order to explore size effects. We find that infrared phonons display strong frequency shifts with decreasing size whereas the Raman modes are nearly rigid, trends that a Davydov splitting analysis attributes to changes in chemical bonding. At low temperature, the intralayer bonding is strengthened below $d_{\text{crit}}$ such that the lattice may not be able to dimerize, thereby blocking the spin-Peierls transition. These findings advance the understanding of cooperative phase transitions and size effects in low-dimensional oxides.

**Methods.** CuGeO$_3$ nanorods were prepared by hydrothermal methods as described previously\textsuperscript{13} and characterized using scanning electron microscopy and X-ray diffraction (Figures 1 and S1). Polycrystalline samples were prepared for comparison by floating zone techniques using an image furnace.\textsuperscript{57} Samples were mixed with a transparent matrix (paraffin or KBr) to form pressed pellets. Infrared transmittance measurements (20–2000 cm$^{-1}$, 1–4 cm$^{-1}$ resolution) were carried out with Bruker 113v and Equinox 55 spectrometers. Absorption was calculated as $\alpha(\omega) = \frac{\pi}{2} \ln(T(\omega))$, where \( h \) is sample loading, $d$ is thickness, and $T(\omega)$ is measured transmittance. Raman spectra (70–1000 cm$^{-1}$) of powders were acquired with an 1800g/mm grating, integration times of 60 s, and averaged three times. The larger sizes were measured using a 532 nm laser with a power of 25 mW, while for the smallest sizes a 473 nm laser\textsuperscript{58,59} with power below 5 mW was employed to prevent sample degradation. Temperature control was achieved with an open flow helium cryostat (4.2–300 K). Standard peak fitting procedures were employed as appropriate.
