

Iron-Carbon Phase  
Diagram (a review) see  
Callister Chapter 9

## The Iron–Iron Carbide (Fe–Fe<sub>3</sub>C) Phase Diagram

In their simplest form, steels are alloys of Iron (Fe) and Carbon (C). The Fe-C phase diagram is a fairly complex one, but we will only consider the steel part of the diagram, up to around 7% Carbon.

## Phases in Fe–Fe<sub>3</sub>C Phase Diagram

- **$\alpha$ -ferrite - solid solution of C in BCC Fe**
  - Stable form of iron at room temperature.
  - The maximum solubility of C is 0.022 wt%
  - Transforms to FCC  $\gamma$ -austenite at 912 °C
  
- **$\gamma$ -austenite - solid solution of C in FCC Fe**
  - The maximum solubility of C is 2.14 wt %.
  - Transforms to BCC  $\delta$ -ferrite at 1395 °C
  - Is not stable below the eutectic temperature (727 °C) unless cooled rapidly (Chapter 10)
  
- **$\delta$ -ferrite solid solution of C in BCC Fe**
  - The same structure as  $\alpha$ -ferrite
  - Stable only at high T, above 1394 °C
  - Melts at 1538 °C
  
- **Fe<sub>3</sub>C (iron carbide or cementite)**
  - This intermetallic compound is metastable, it remains as a compound indefinitely at room T, but decomposes (very slowly, within several years) into  $\alpha$ -Fe and C (graphite) at 650 - 700 °C
  
- **Fe-C liquid solution**

## A few comments on Fe–Fe<sub>3</sub>C system

C is an interstitial impurity in Fe. It forms a solid solution with  $\alpha$ ,  $\gamma$ ,  $\delta$  phases of iron

Maximum solubility in BCC  $\alpha$ -ferrite is limited (max. 0.022 wt% at 727 °C) - BCC has relatively small interstitial positions

Maximum solubility in FCC austenite is 2.14 wt% at 1147 °C - FCC has larger interstitial positions

**Mechanical properties:** Cementite is very hard and brittle - can strengthen steels. Mechanical properties also depend on the microstructure, that is, how ferrite and cementite are mixed.

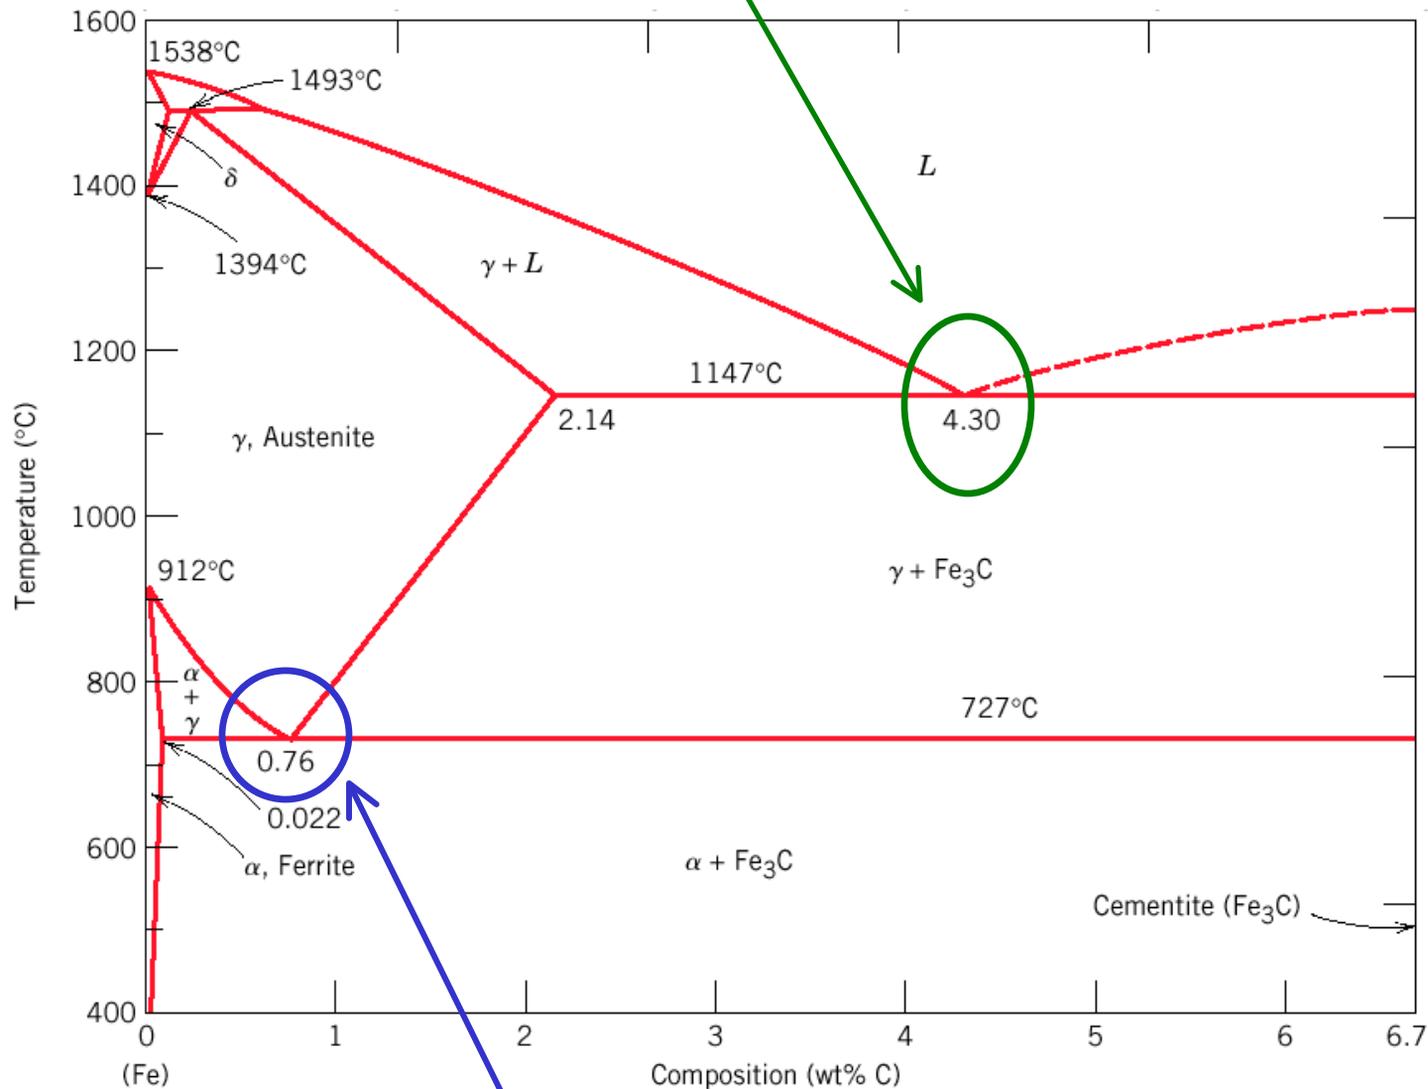

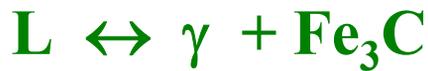

**Magnetic properties:**  $\alpha$  -ferrite is magnetic below 768 °C, austenite is non-magnetic

### Classification. Three types of ferrous alloys:

- **Iron:** less than 0.008 wt % C in  $\alpha$ -ferrite at room T
- **Steels:** 0.008 - 2.14 wt % C (usually < 1 wt %)  $\alpha$ -ferrite + Fe<sub>3</sub>C at room T (Chapter 12)
- **Cast iron:** 2.14 - 6.7 wt % (usually < 4.5 wt %)

## Eutectic and eutectoid reactions in Fe-Fe<sub>3</sub>C

**Eutectic:** 4.30 wt% C, 1147 °C

**Eutectoid:** 0.76 wt%C, 727 °C

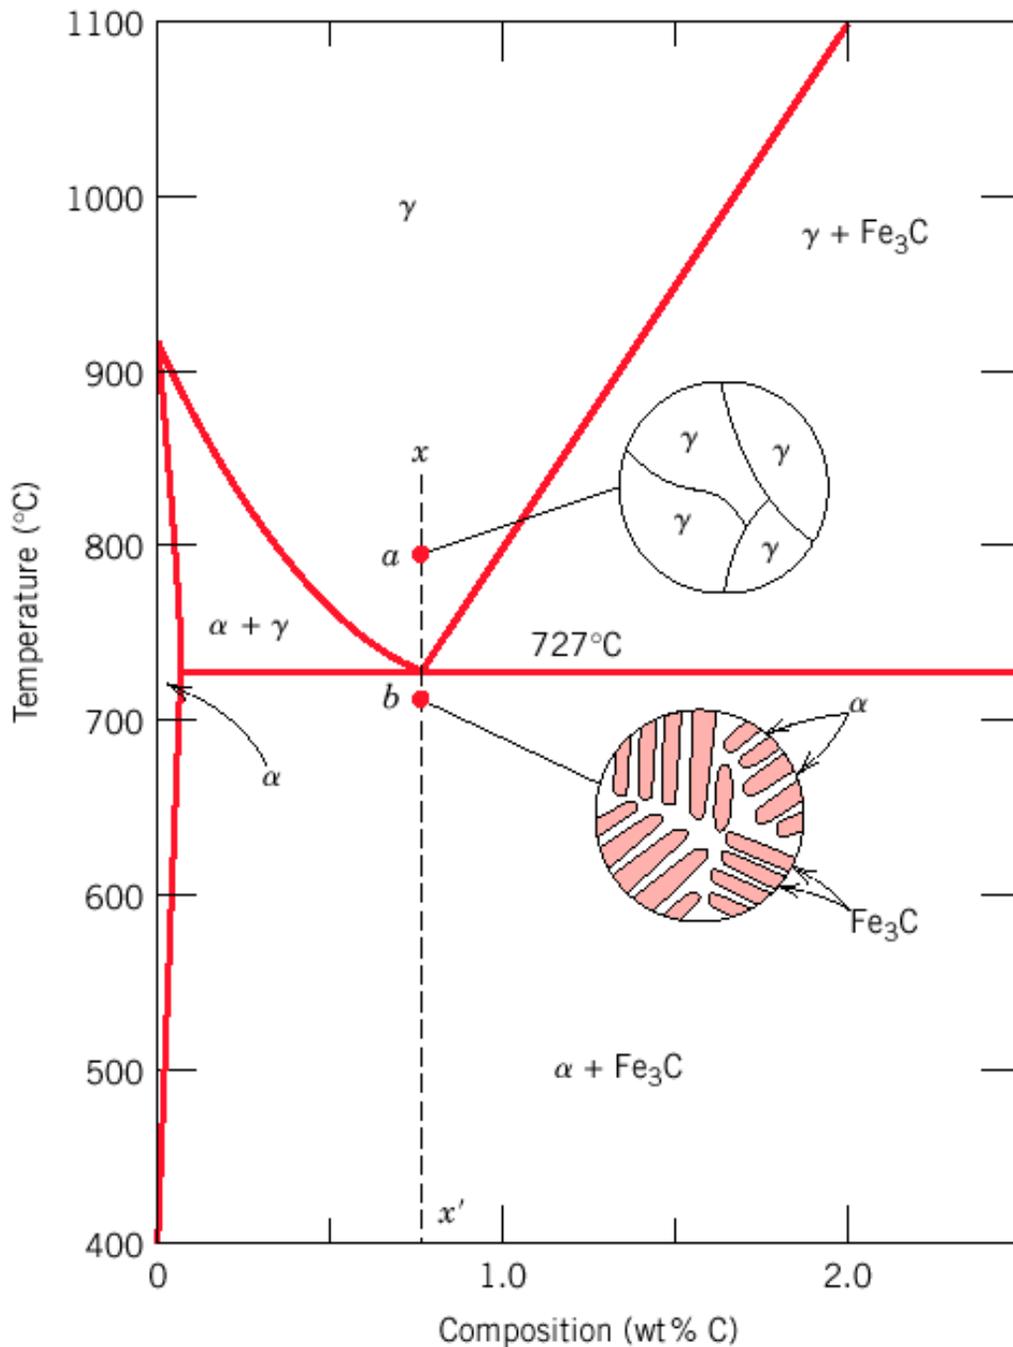

Eutectic and eutectoid reactions are very important in heat treatment of steels

## Development of Microstructure in Iron - Carbon alloys

**Microstructure depends on composition (carbon content) and heat treatment.** In the discussion below we consider slow cooling in which equilibrium is maintained.

### Microstructure of eutectoid steel (I)

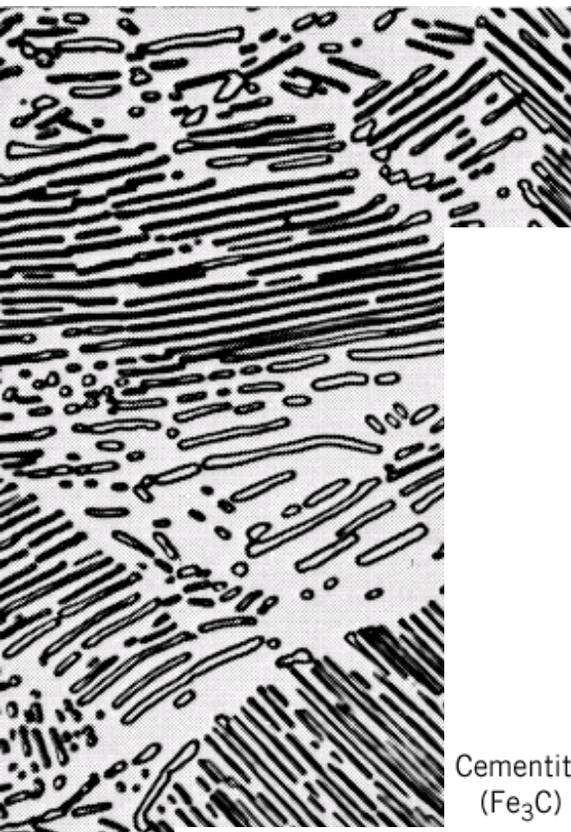

## Microstructure of eutectoid steel (II)

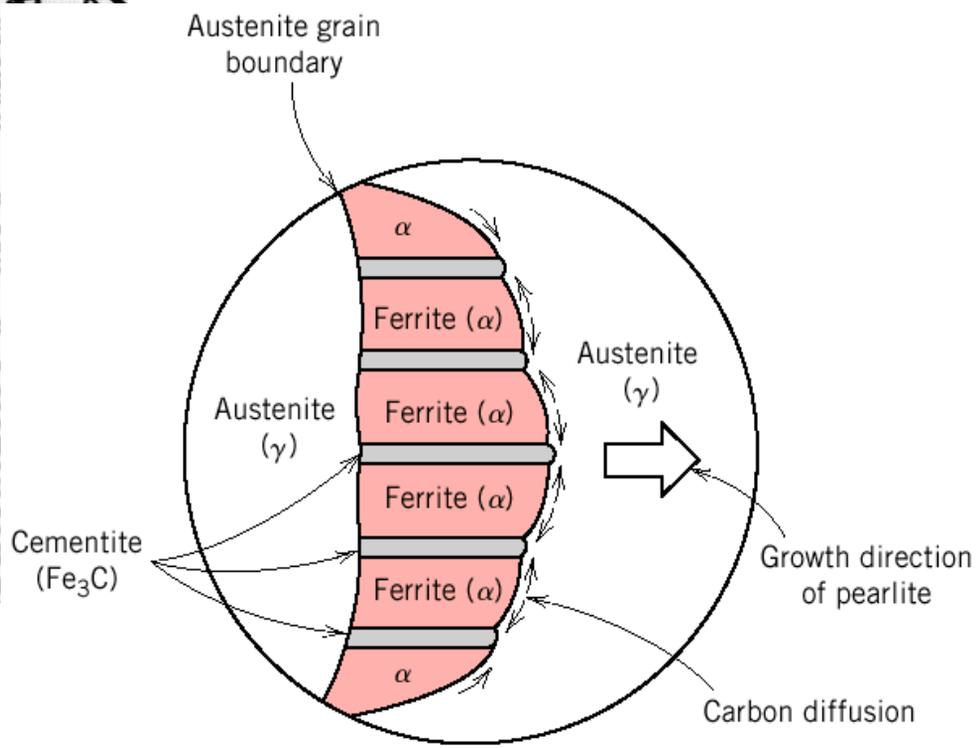

When alloy of eutectoid composition (0.76 wt % C) is cooled slowly it forms **pearlite**, a lamellar or layered structure of two phases:  $\alpha$ -ferrite and cementite ( $\text{Fe}_3\text{C}$ )

The layers of alternating phases in pearlite are formed for the same reason as layered structure of eutectic structures: redistribution C atoms between ferrite (0.022 wt%) and cementite (6.7 wt%) by atomic diffusion.

Mechanically, pearlite has properties intermediate to soft, ductile ferrite and hard, brittle cementite.

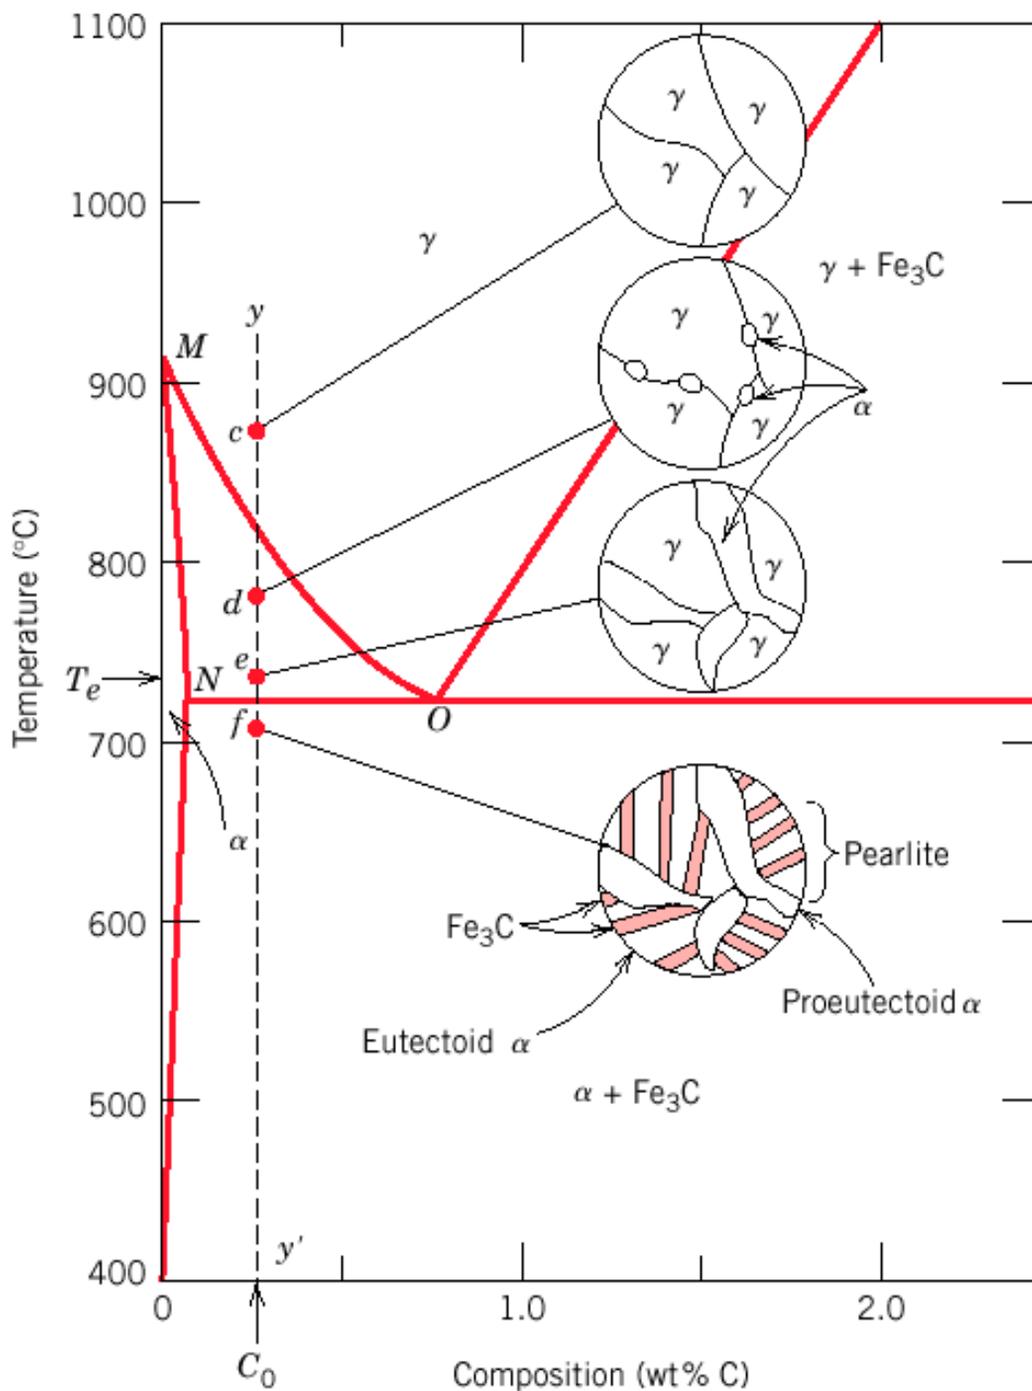

In the micrograph, the dark areas are  $\text{Fe}_3\text{C}$  layers, the light phase is  $\alpha$ -ferrite

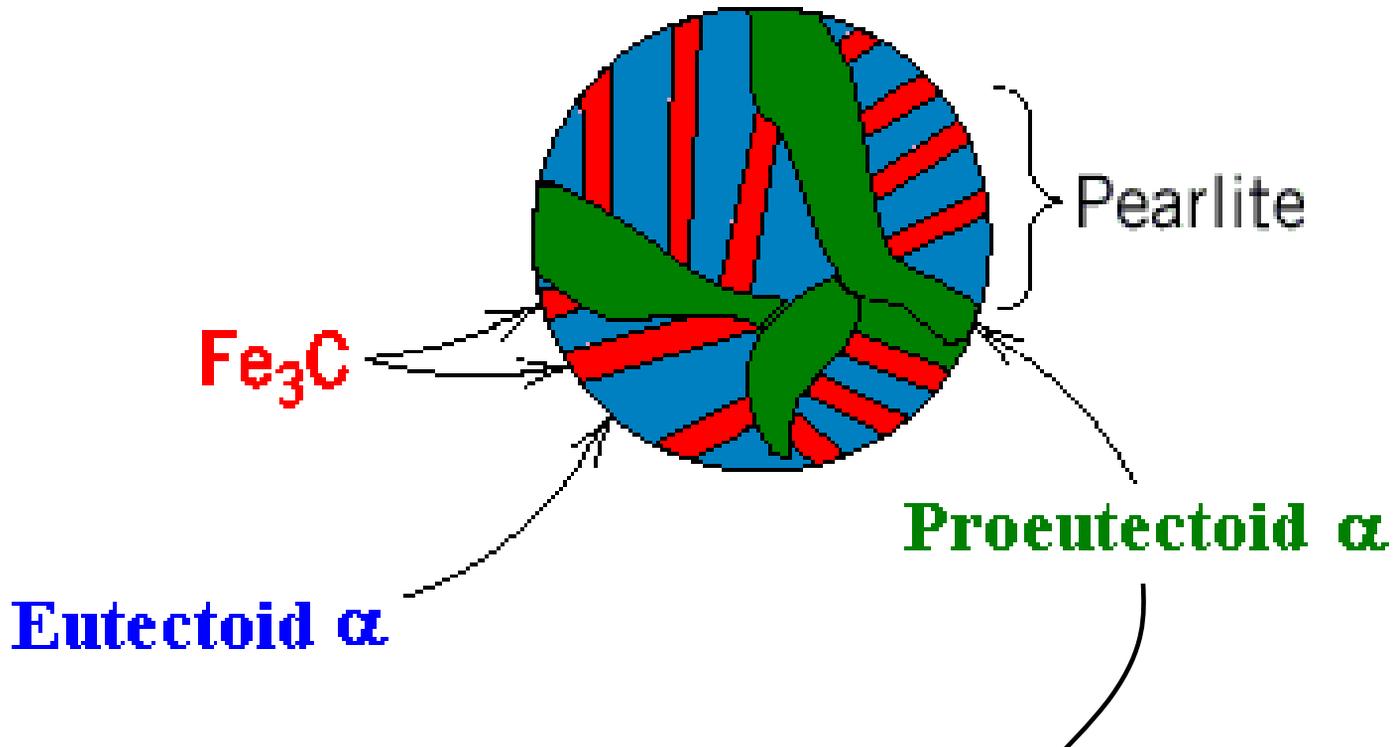

## Microstructure of **hypoeutectoid** steel (I)

Compositions to the left of eutectoid (0.022 - 0.76 wt % C)  
**hypoeutectoid** (*less than eutectoid* -Greek) alloys.

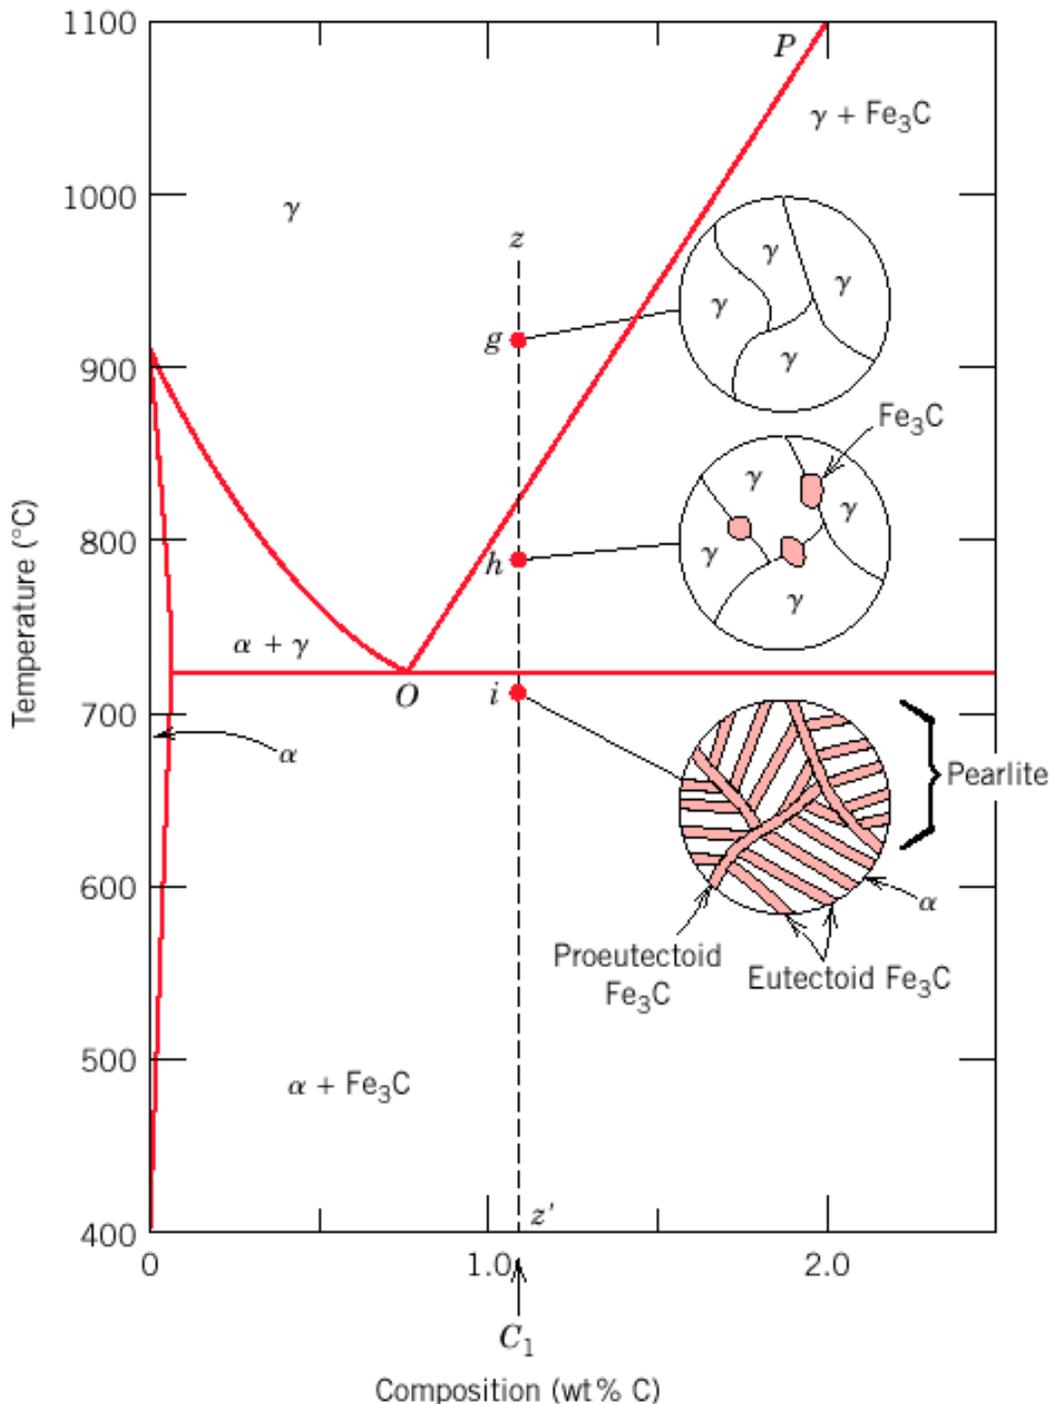

## Microstructure of **hypoeutectoid** steel (II)

Hypoeutectoid alloys contain proeutectoid ferrite (formed above the eutectoid temperature) plus the eutectoid perlite that contain eutectoid ferrite and cementite.

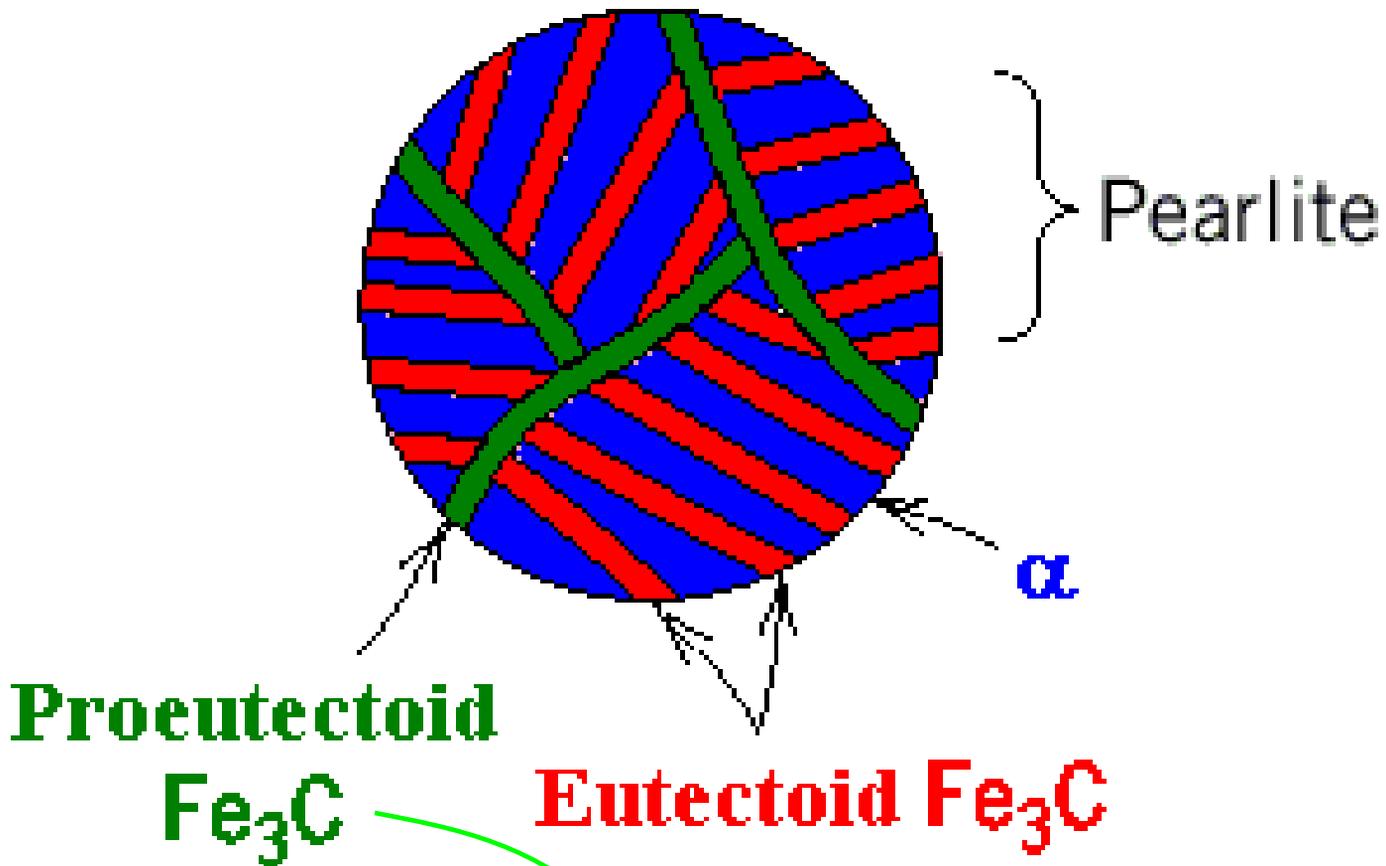

# Microstructure of **hypereutectoid steel (I)**

Compositions to the right of eutectoid (0.76 - 2.14 wt % C)  
**hypereutectoid** (*more than eutectoid* -Greek) alloys.

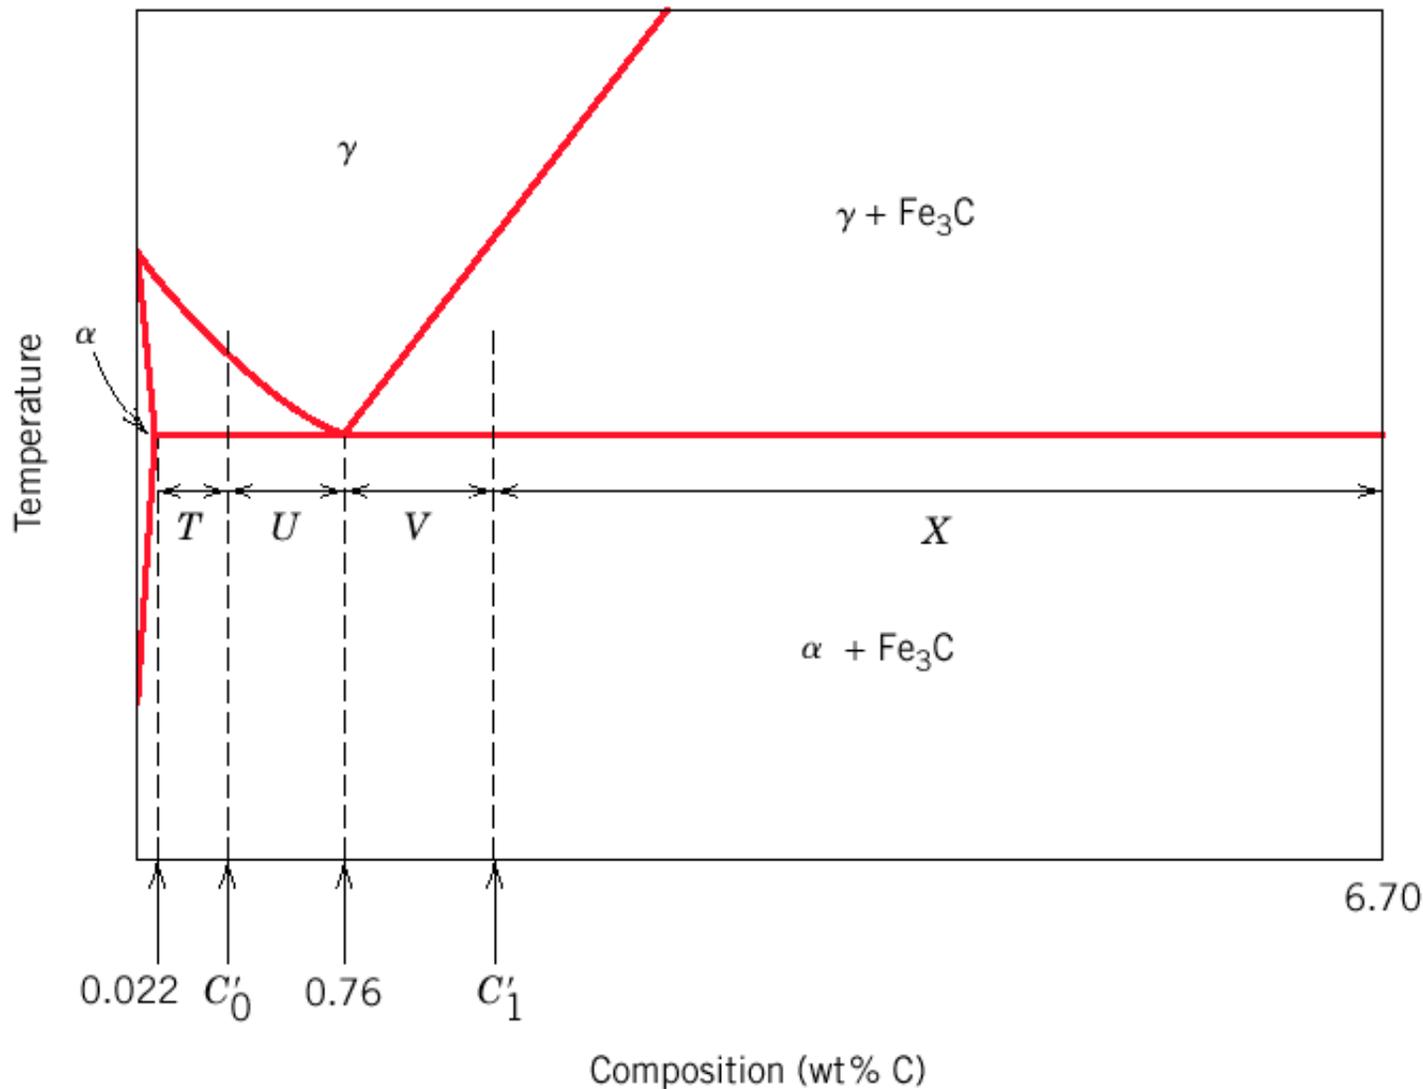

## Microstructure of hypereutectoid steel (II)

Hypereutectoid alloys contain proeutectoid cementite (formed above the eutectoid temperature) plus pearlite that contain eutectoid ferrite and cementite.

## How to calculate the relative amounts of proeutectoid phase ( $\alpha$ or $\text{Fe}_3\text{C}$ ) and pearlite?

Application of the lever rule with tie line that extends from the eutectoid composition (0.76 wt% C) to  $\alpha - (\alpha + \text{Fe}_3\text{C})$  boundary (0.022 wt% C) for hypoeutectoid alloys and to  $(\alpha + \text{Fe}_3\text{C}) - \text{Fe}_3\text{C}$  boundary (6.7 wt% C) for hypereutectoid alloys.

Fraction of  $\alpha$  phase is determined by application of the lever rule across the entire  $(\alpha + \text{Fe}_3\text{C})$  phase field:

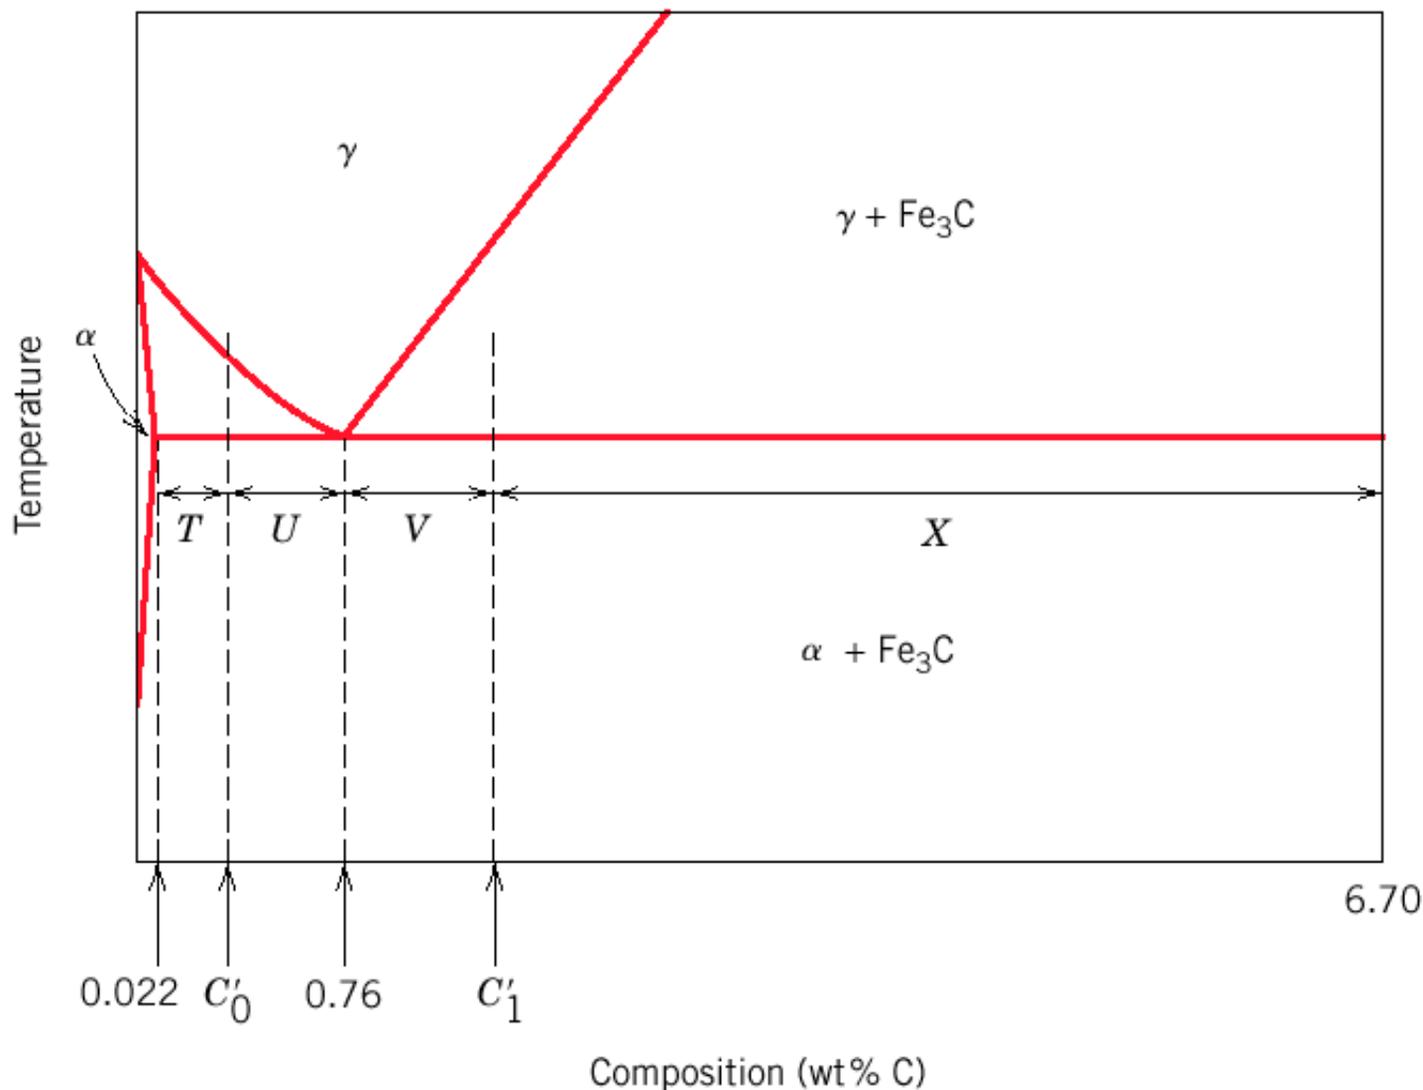

Example for hypereutectoid alloy with composition  $C_1$ 

Fraction of pearlite:

$$W_P = X / (V+X) = (6.7 - C_1) / (6.7 - 0.76)$$

Fraction of proeutectoid cementite:

$$W_{Fe_3C} = V / (V+X) = (C_1 - 0.76) / (6.7 - 0.76)$$

Phase Transformations  
of Fe-C (a review)  
see Callister Chapter 10

## Phase transformations. Kinetics.

**Phase transformations** (change of the microstructure) can be divided into three categories:

- **Diffusion-dependent with no change in phase composition or number of phases present** (e.g. melting, solidification of pure metal, allotropic transformations, recrystallization, etc.)
- **Diffusion-dependent with changes in phase compositions and/or number of phases** (e.g. eutectoid transformations)
- **Diffusionless phase transformation** - produces a metastable phase by cooperative small displacements of all atoms in structure (e.g. martensitic transformation discussed in later in this chapter)

Phase transformations do not occur instantaneously. Diffusion-dependent phase transformations can be rather slow and the final structure often depend on the rate of cooling/heating.

**We need to consider the time dependence or kinetics of the phase transformations.**

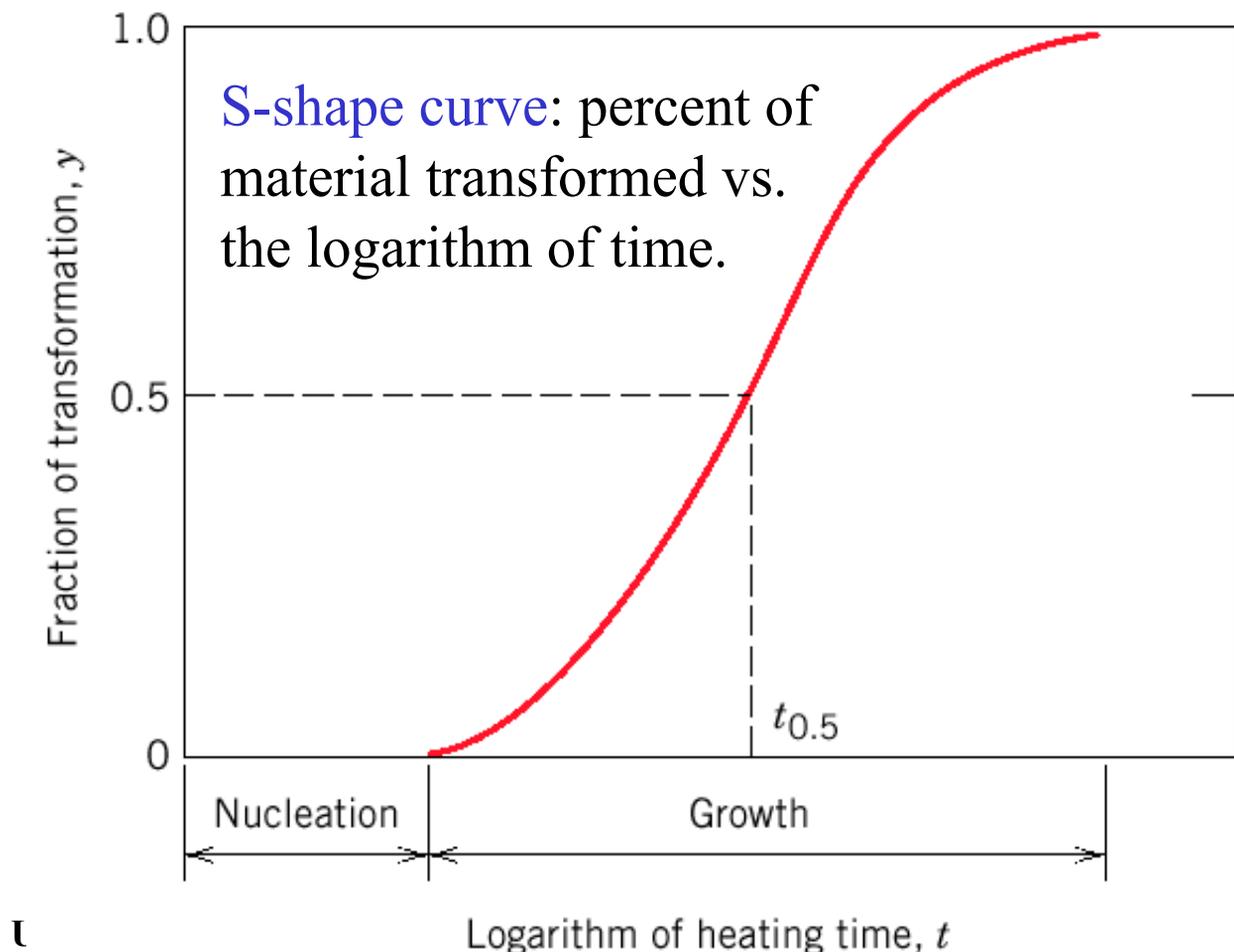

## Kinetics of phase transformations

Most phase transformations involve change in composition  
 $\Rightarrow$  redistribution of atoms via diffusion is required.

The process of phase transformation involves:

- **Nucleation** of of the new phase - formation of stable small particles (nuclei) of the new phase. Nuclei are often formed at grain boundaries and other defects.
- **Growth** of new phase at the expense of the original phase.

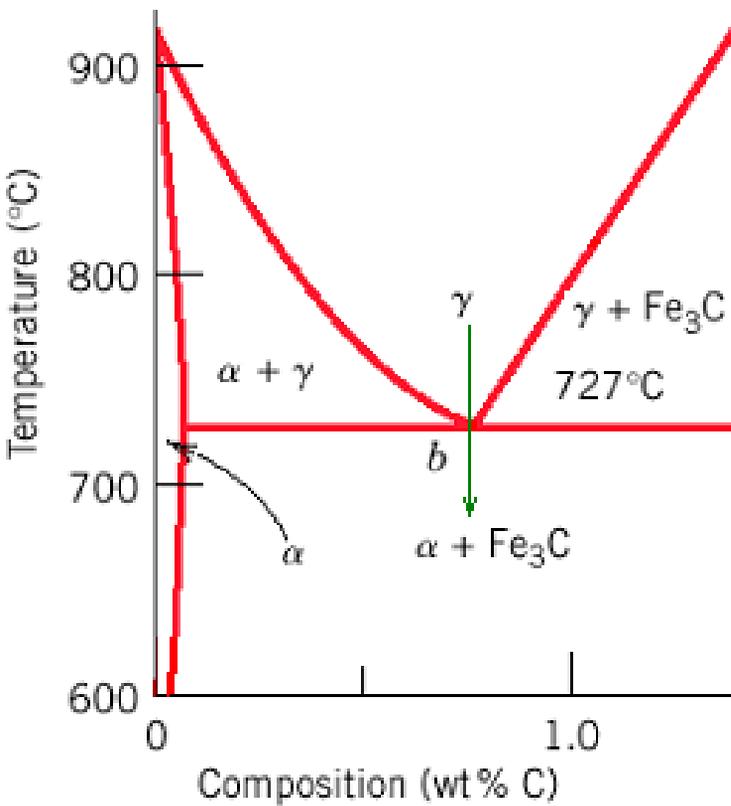

$$y = 1 - \exp(-kt^n) \quad \text{Avrami Equation}$$

## Superheating / supercooling

- Upon crossing a phase boundary on the composition-temperature phase diagram phase transformation towards equilibrium state is induced.
- But the transition to the equilibrium structure takes time and transformation is delayed.
- During cooling, transformations occur at temperatures less than predicted by phase diagram: **supercooling**.
- During heating, transformations occur at temperatures greater than predicted by phase diagram: **superheating**.
- Degree of supercooling/superheating increases with rate of cooling/heating.
- **Metastable states** can be formed as a result of fast temperature change. **Microstructure is strongly affected by the rate of cooling.**
- Below we will consider the effect of time on phase transformations using iron-carbon alloy as an example.

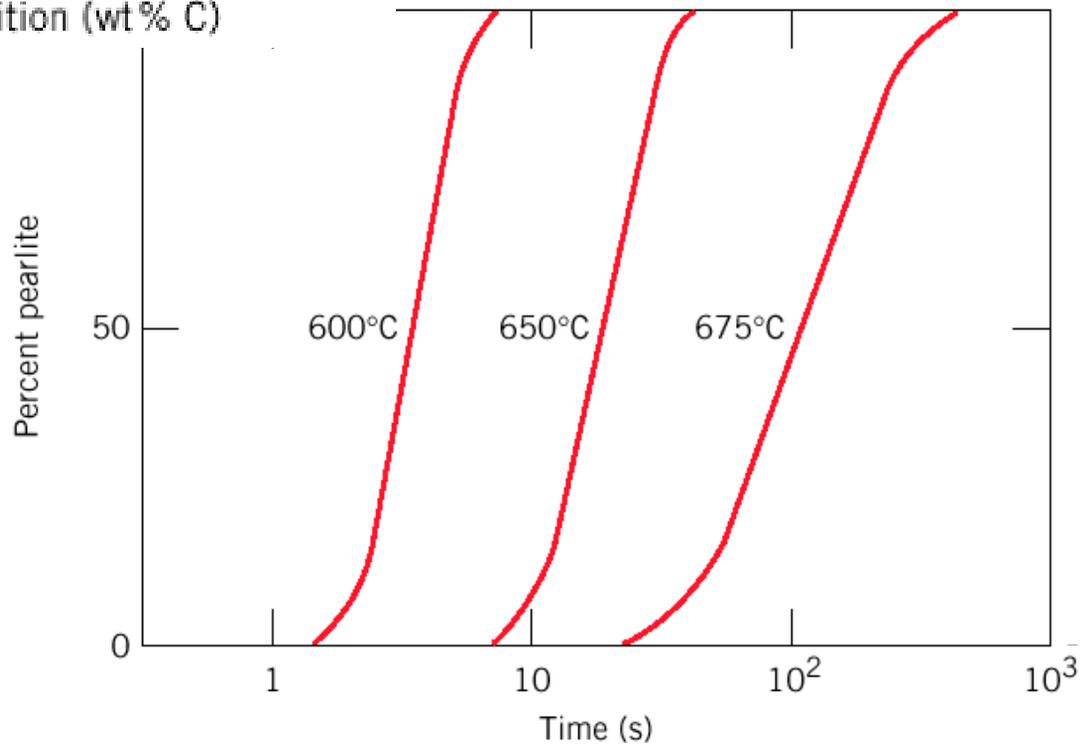

# Let us consider eutectoid reaction as an example

eutectoid reaction:

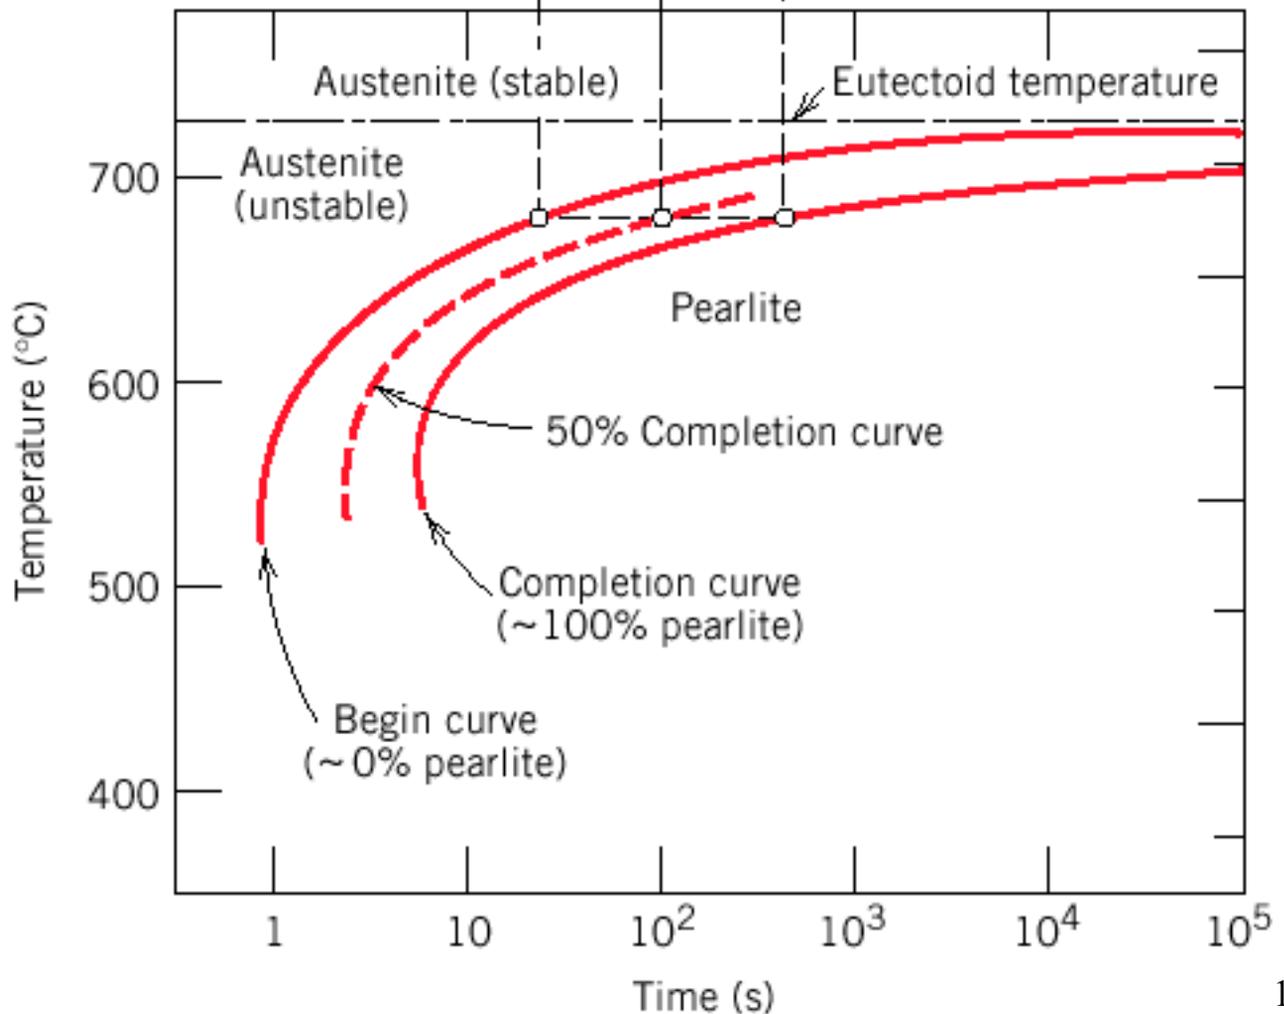

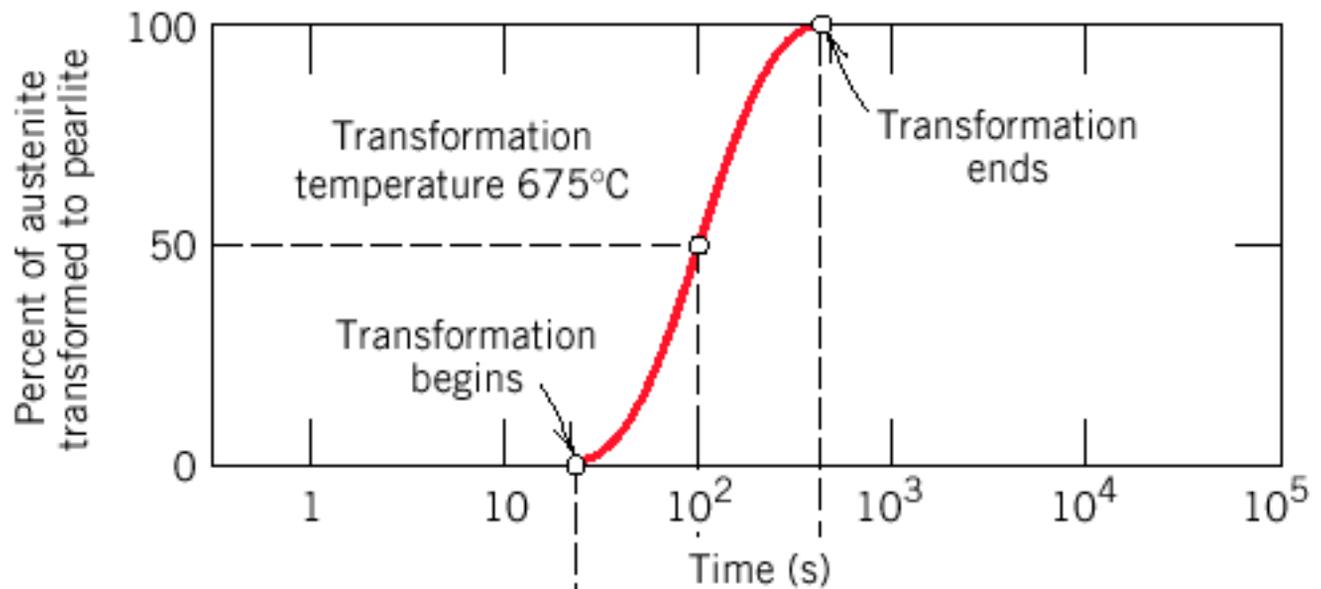

+

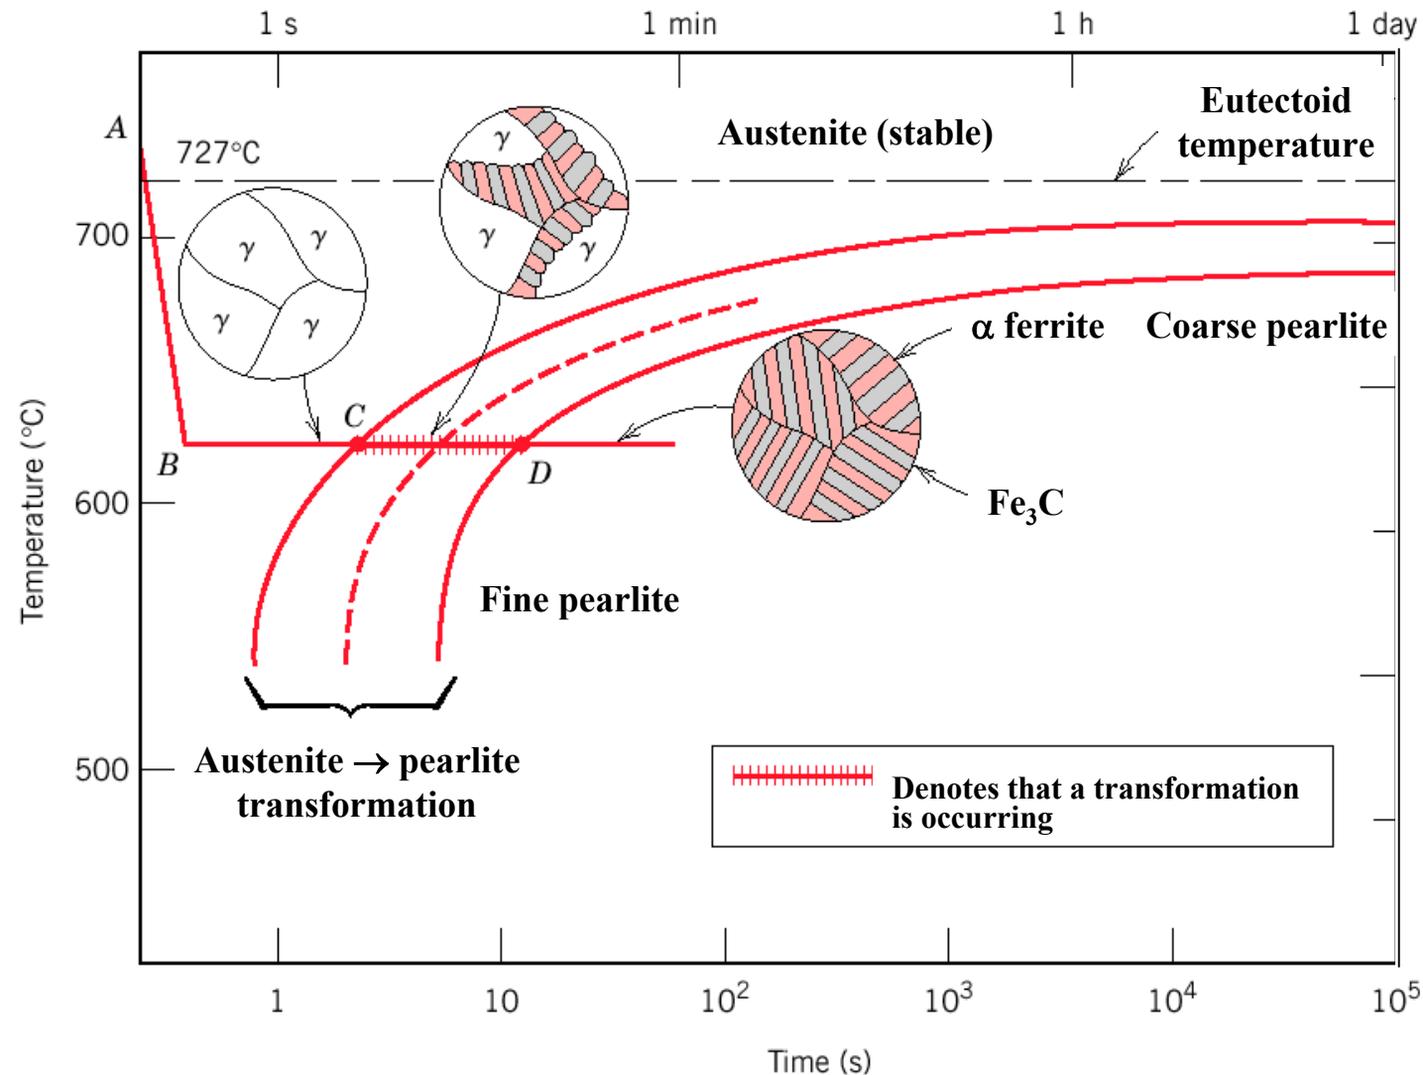

The S-shaped curves are shifted to longer times at higher T showing that the transformation is dominated by nucleation (nucleation rate increases with supercooling) and not by diffusion (which occurs faster at higher T).

# Isothermal Transformation (or TTT) Diagrams (Temperature, Time, and % Transformation)

# TTT Diagrams

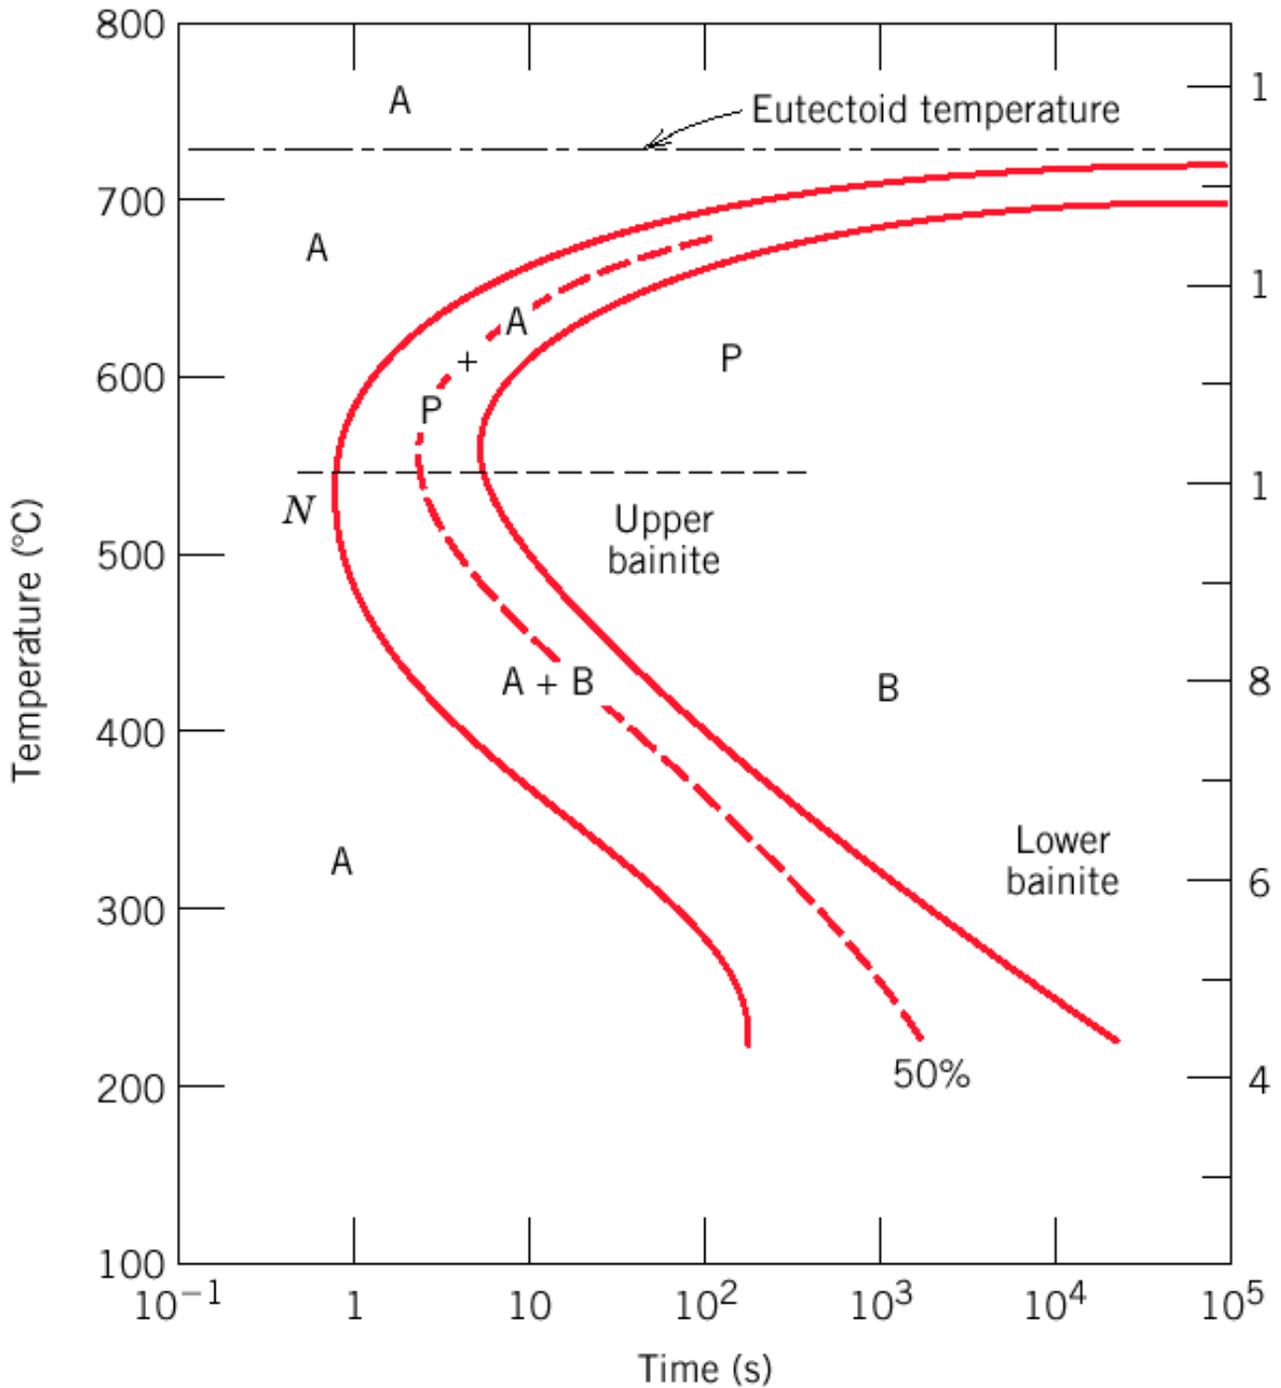

The thickness of the ferrite and cementite layers in pearlite is  $\sim 8:1$ . The absolute layer thickness depends on the temperature of the transformation. The higher the temperature, the thicker the layers.

## TTT Diagrams

- The family of S-shaped curves at different T are used to construct the TTT diagrams.
- The TTT diagrams are for the **isothermal** (constant T) transformations (material is cooled quickly to a given temperature before the transformation occurs, and then keep it at that temperature).
- At low temperatures, the transformation occurs sooner (it is controlled by the rate of nucleation) and grain growth (that is controlled by diffusion) is reduced.
- Slow diffusion at low temperatures leads to fine-grained microstructure with thin-layered structure of pearlite (**fine pearlite**).
- At higher temperatures, high diffusion rates allow for larger grain growth and formation of thick layered structure of pearlite (**coarse pearlite**).
- At compositions other than eutectoid, a proeutectoid phase (ferrite or cementite) coexist with pearlite. Additional curves for proeutectoid transformation must be included on TTT diagrams.

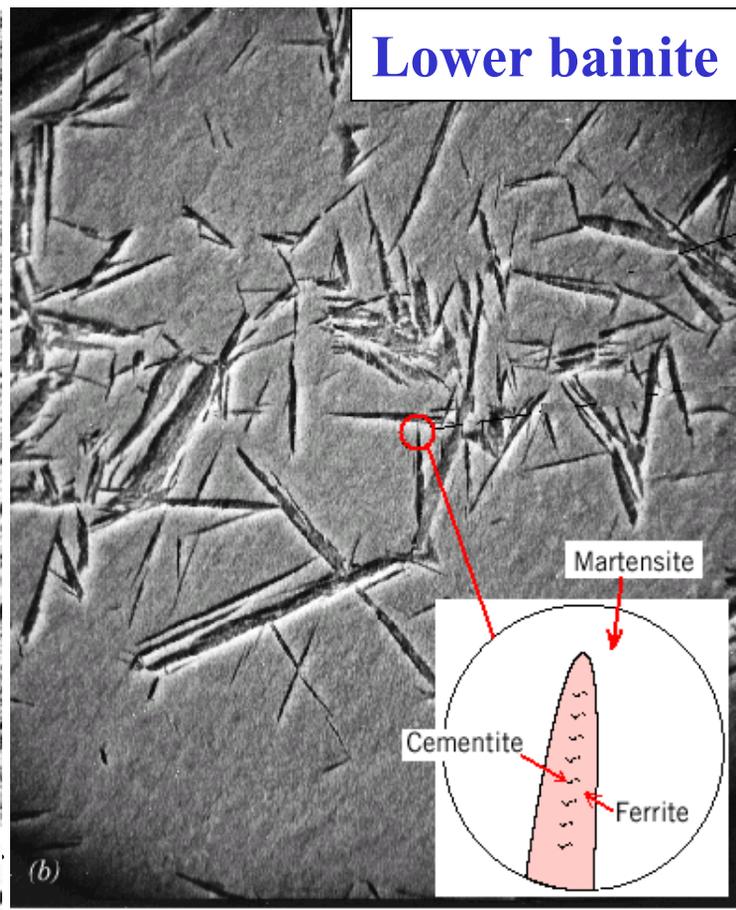

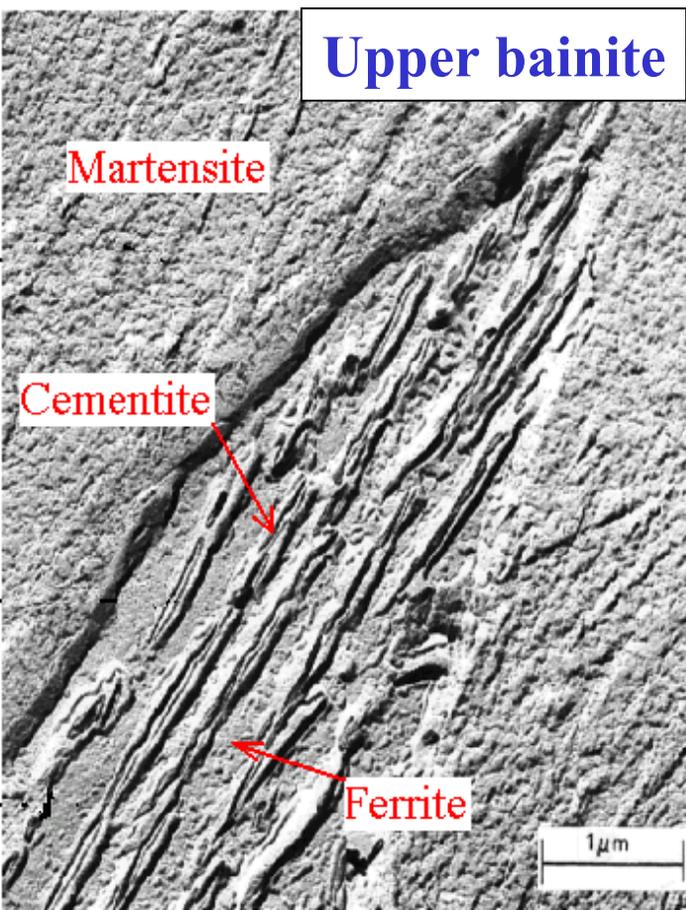

## Formation of Bainite Microstructure (I)

If transformation temperature is low enough ( $\leq 540^\circ\text{C}$ ) bainite rather than fine pearlite forms.

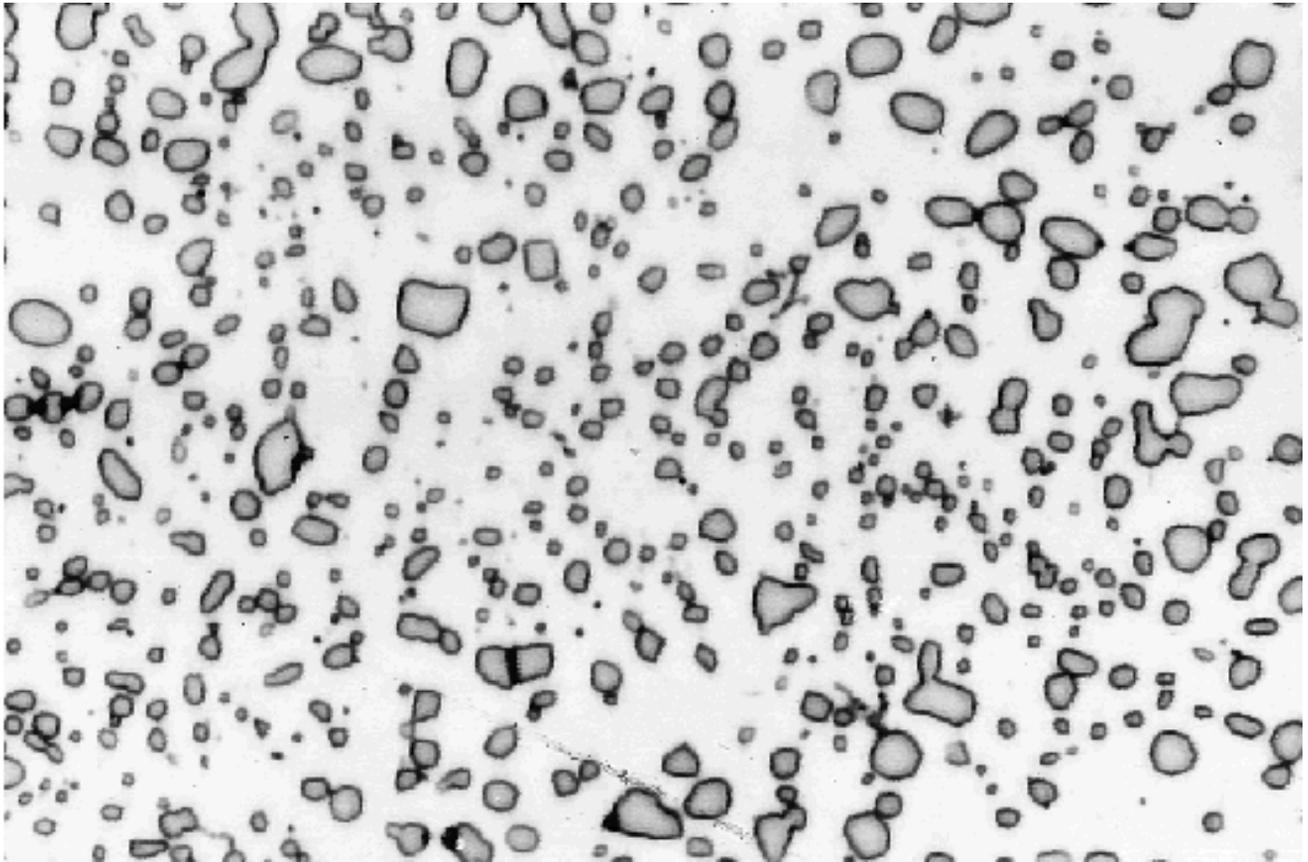

## Formation of Bainite Microstructure (II)

- For  $T \sim 300\text{-}540^\circ\text{C}$ , **upper bainite** consists of needles of ferrite separated by long cementite particles
- For  $T \sim 200\text{-}300^\circ\text{C}$ , **lower bainite** consists of thin plates of ferrite containing very fine rods or blades of cementite
- In the bainite region, transformation rate is controlled by microstructure growth (diffusion) rather than nucleation. Since diffusion is slow at low temperatures, this phase has a very fine (microscopic) microstructure.
- Pearlite and bainite transformations are competitive; transformation between pearlite and bainite not possible without first reheating to form austenite

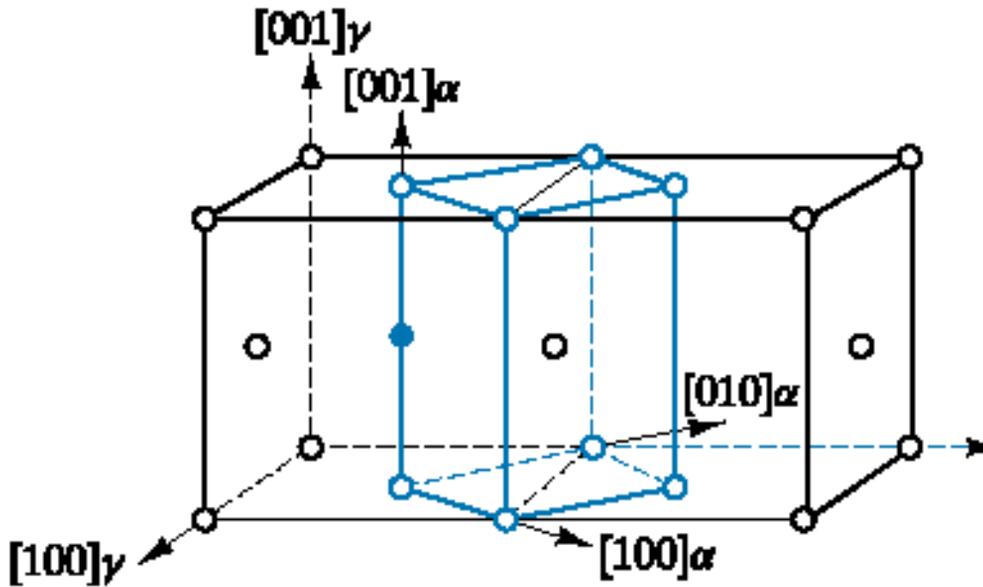

## Spheroidite

- Annealing of pearlitic or bainitic microstructures at elevated temperatures just below eutectoid (e.g. 24 h at 700 C) leads to the formation of new microstructure – **spheroidite** - spheres of cementite in a ferrite matrix.
- Composition or relative amounts of ferrite and cementite are not changing in this transformation, **only shape of the cementite inclusions is changing.**
- Transformation proceeds by C diffusion – needs high T.
- Driving force for the transformation - reduction in total ferrite - cementite boundary area

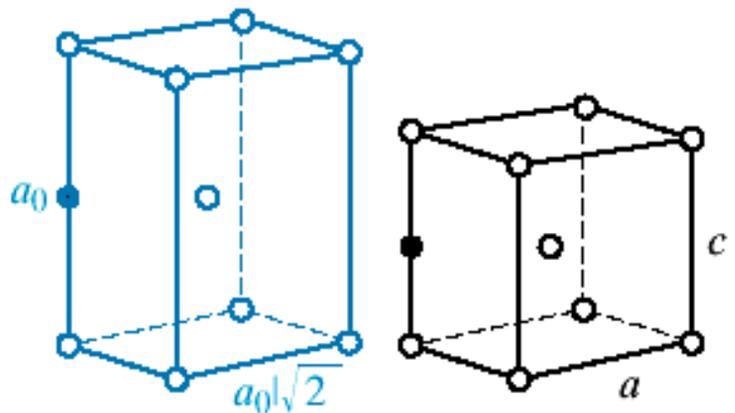

## Martensite (I)

- Martensite forms when austenite is rapidly cooled (**quenched**) to room T.
- It forms nearly instantaneously when the required low temperature is reached. The austenite-martensite **does not involve diffusion** → no thermal activation is needed, this is called an **athermal transformation**.
- Each atom displaces a small (sub-atomic) distance to transform FCC  $\gamma$ -Fe (austenite) to martensite which has a Body Centered Tetragonal (BCT) unit cell (like BCC, but one unit cell axis is longer than the other two).
- Martensite is **metastable** - can persist indefinitely at room temperature, but will transform to equilibrium phases on annealing at an elevated temperature.
- Martensite can coexist with other phases and/or microstructures in Fe-C system
- Since martensite is metastable non-equilibrium phase, it does not appear in phase Fe-C phase diagram

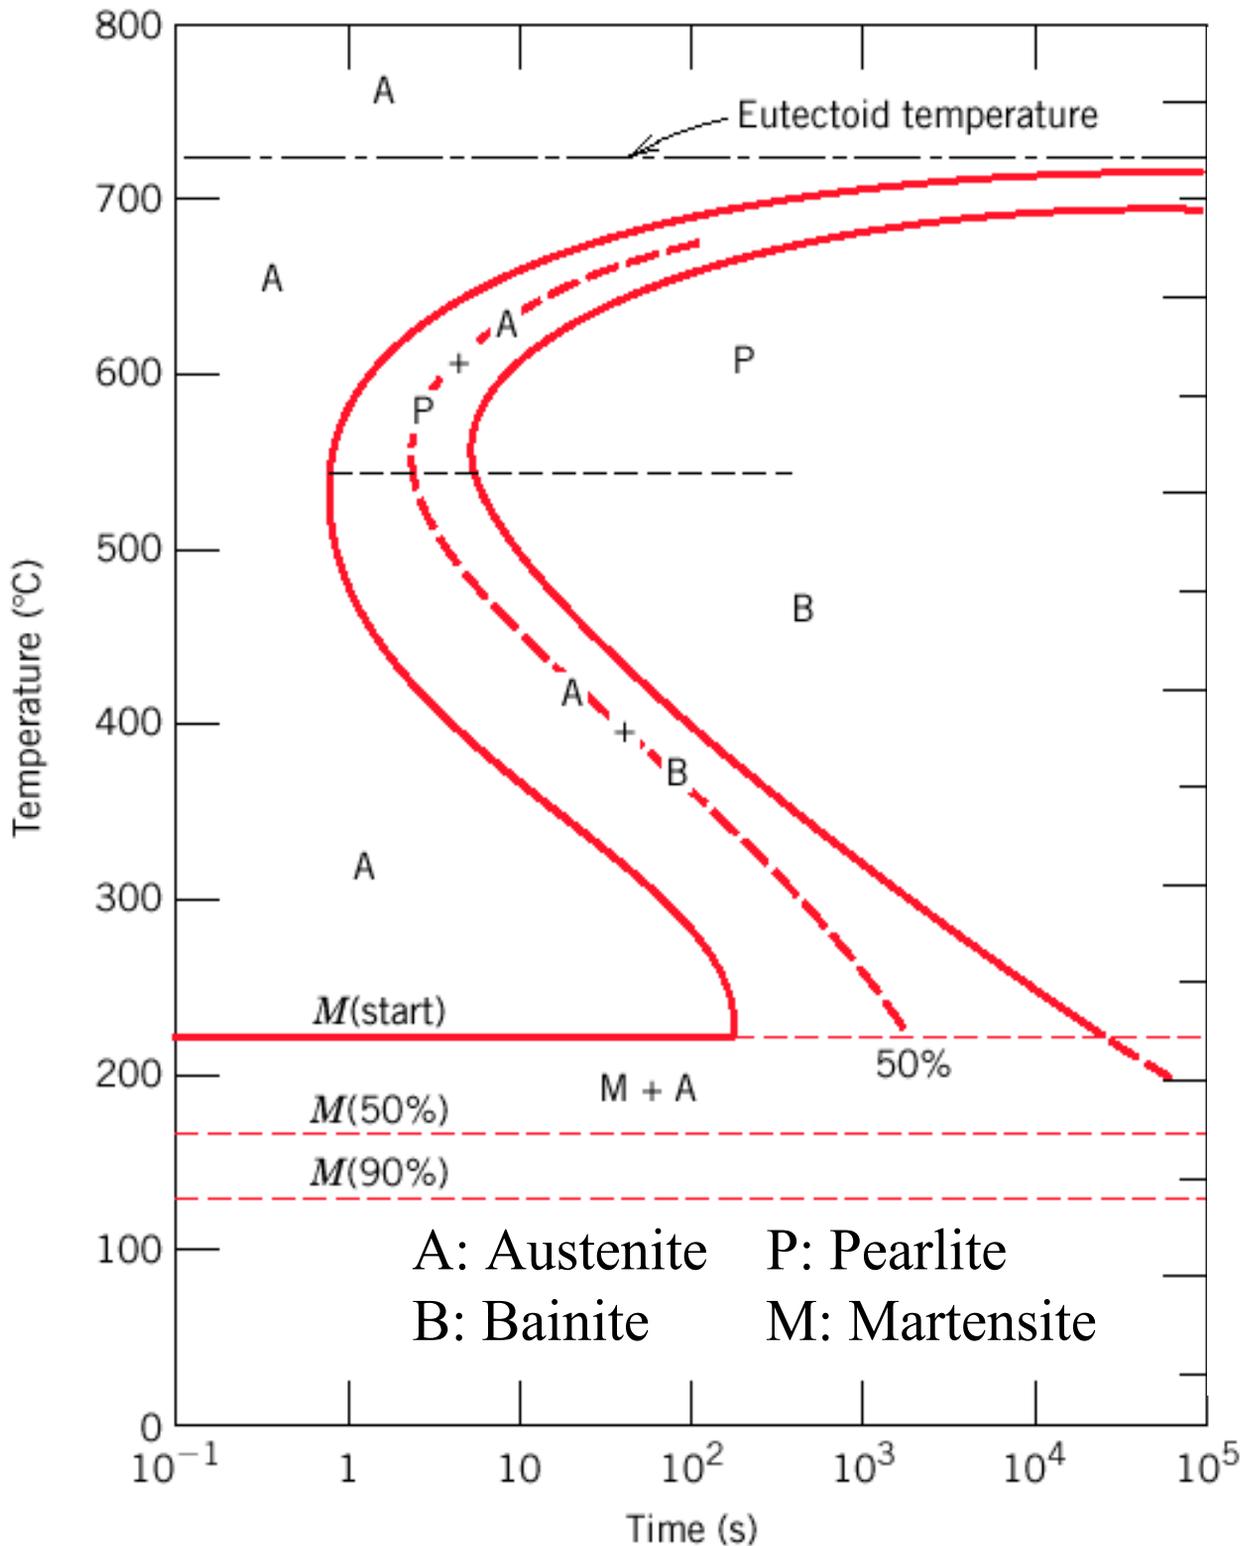

(a)

(b)

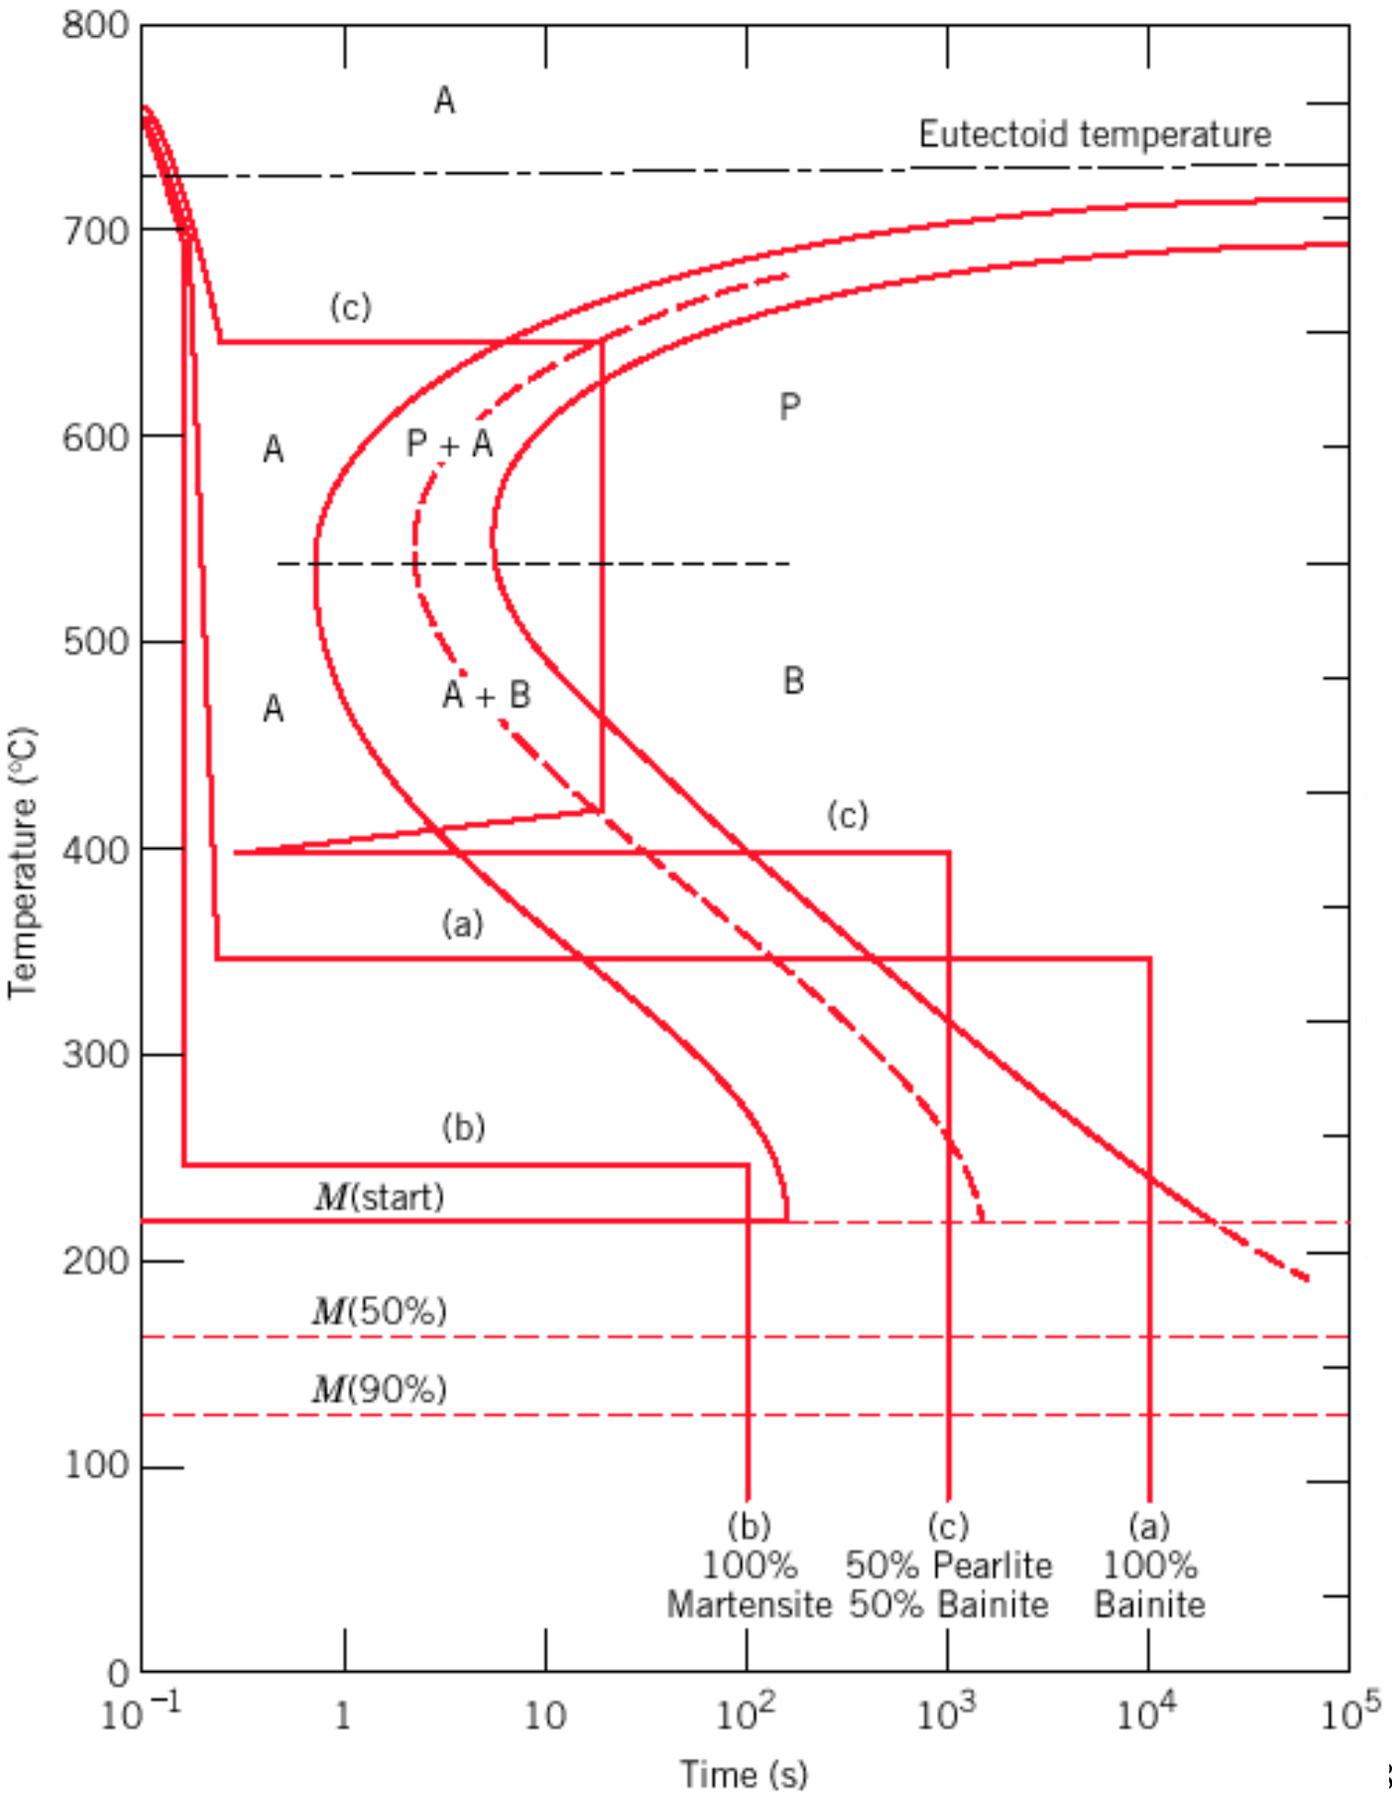

The martensitic transformation involves the sudden reorientation of C and Fe atoms from the FCC solid solution of  $\gamma$ -Fe (austenite) to a body-centered tetragonal (BCT) solid solution (martensite).

# TTT Diagram including Martensite

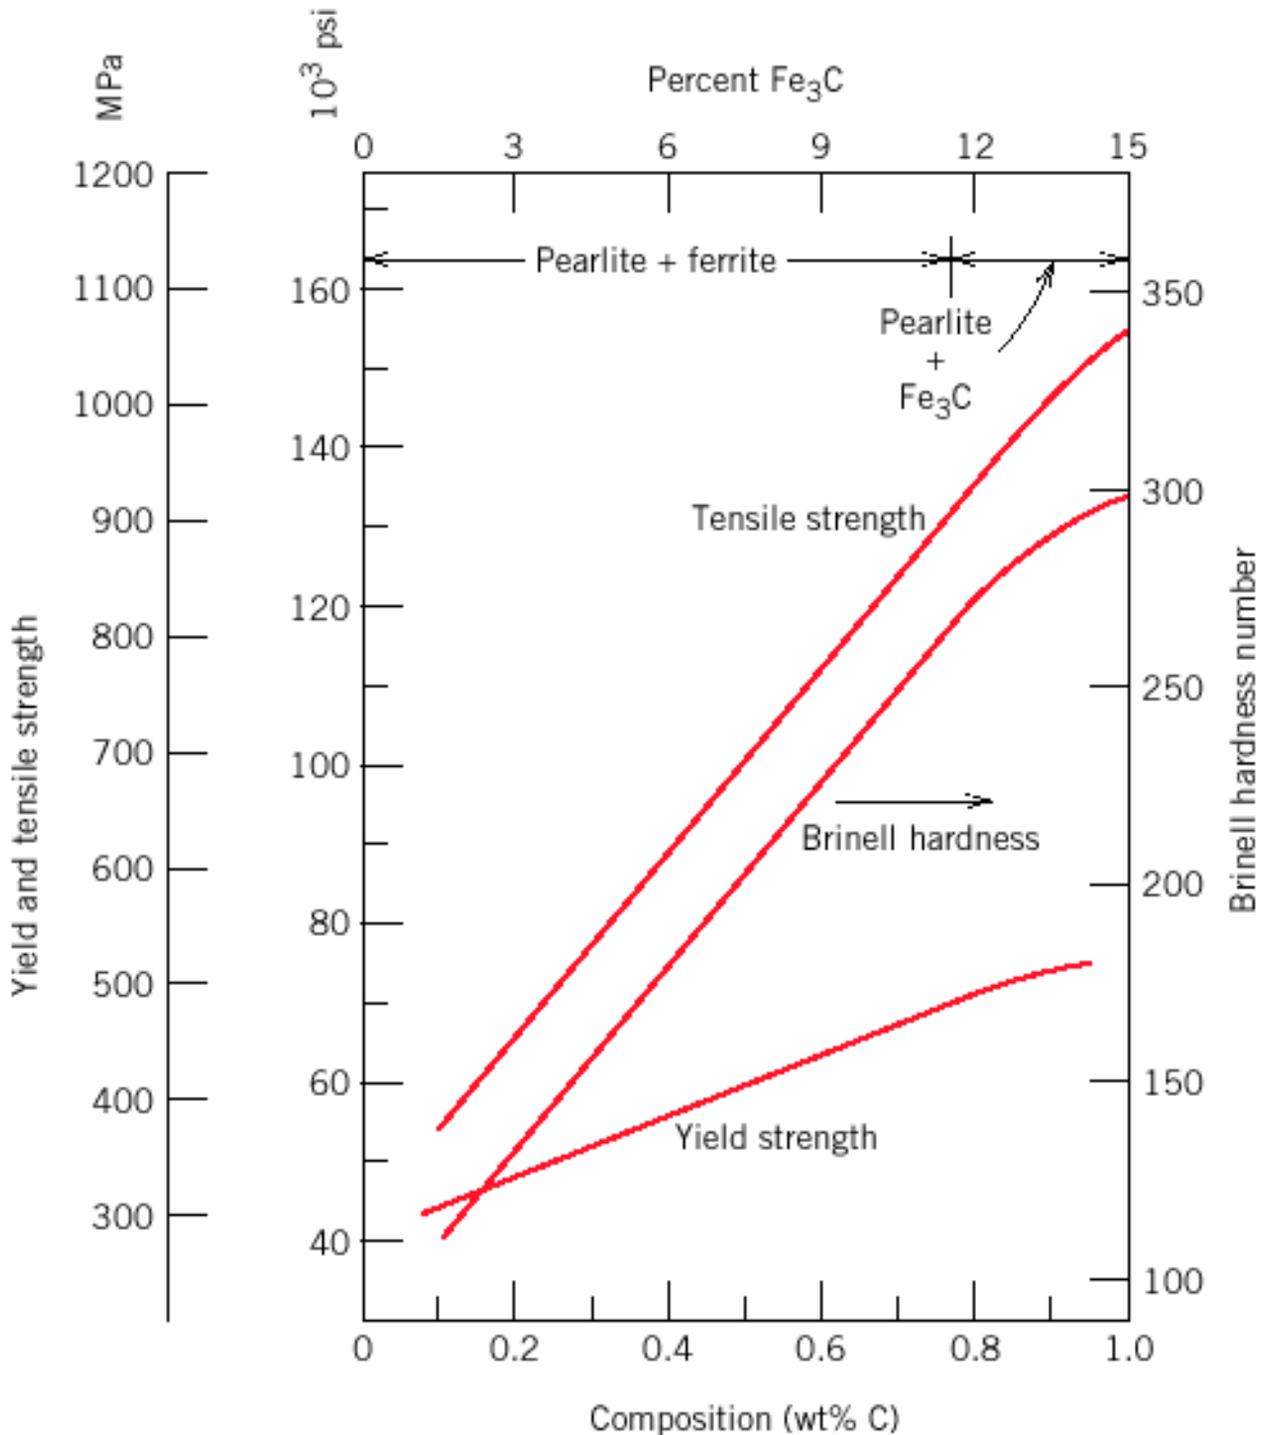

Austenite-to-martensite is diffusionless and very fast. The amount of martensite formed depends on temperature only.

# Time-temperature path – microstructure

## Mechanical Behavior of Fe-C Alloys (I)

Cementite is harder and more brittle than ferrite - increasing cementite fraction therefore makes harder, less ductile material.

## Mechanical Behavior of Fe-C Alloys (II)

The strength and hardness of the different microstructures is inversely related to the size of the microstructures (fine structures have more phase boundaries inhibiting dislocation motion).

### Mechanical properties of bainite, pearlite, spheroidite

Considering microstructure we can predict that

- Spheroidite is the softest
- Fine pearlite is harder and stronger than coarse pearlite
- Bainite is harder and stronger than pearlite

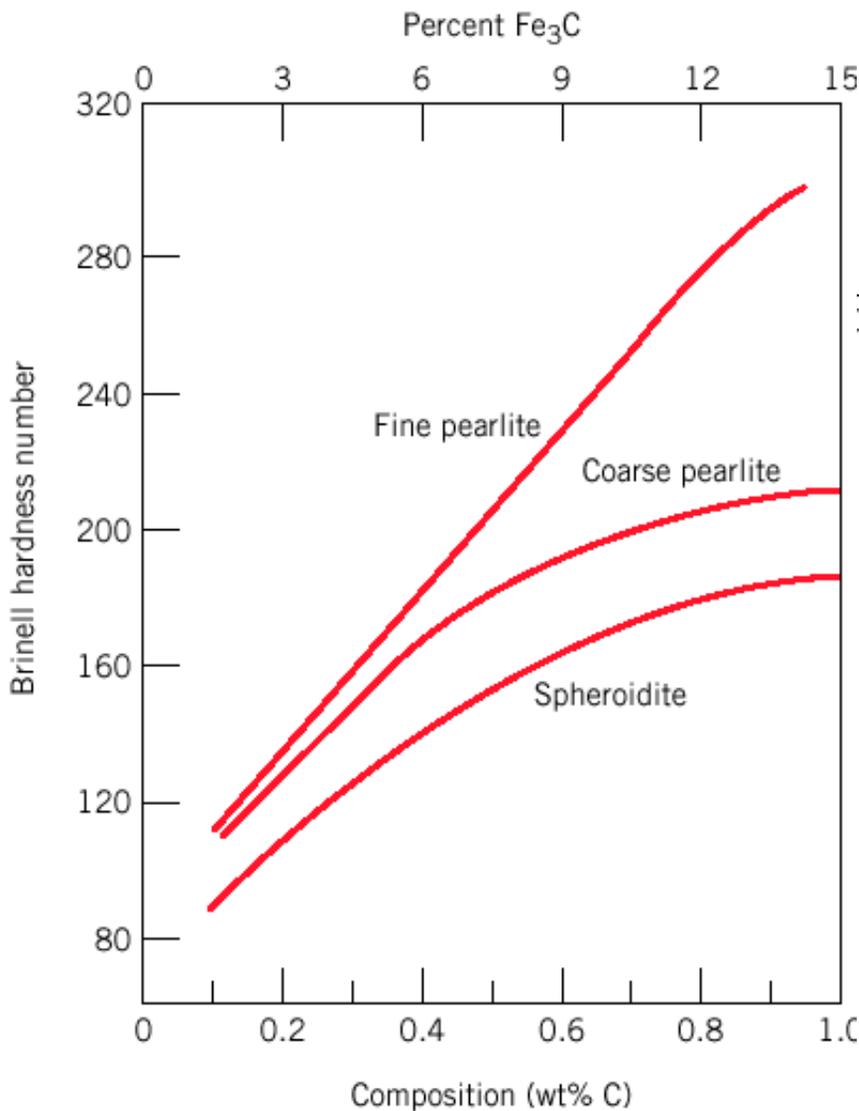

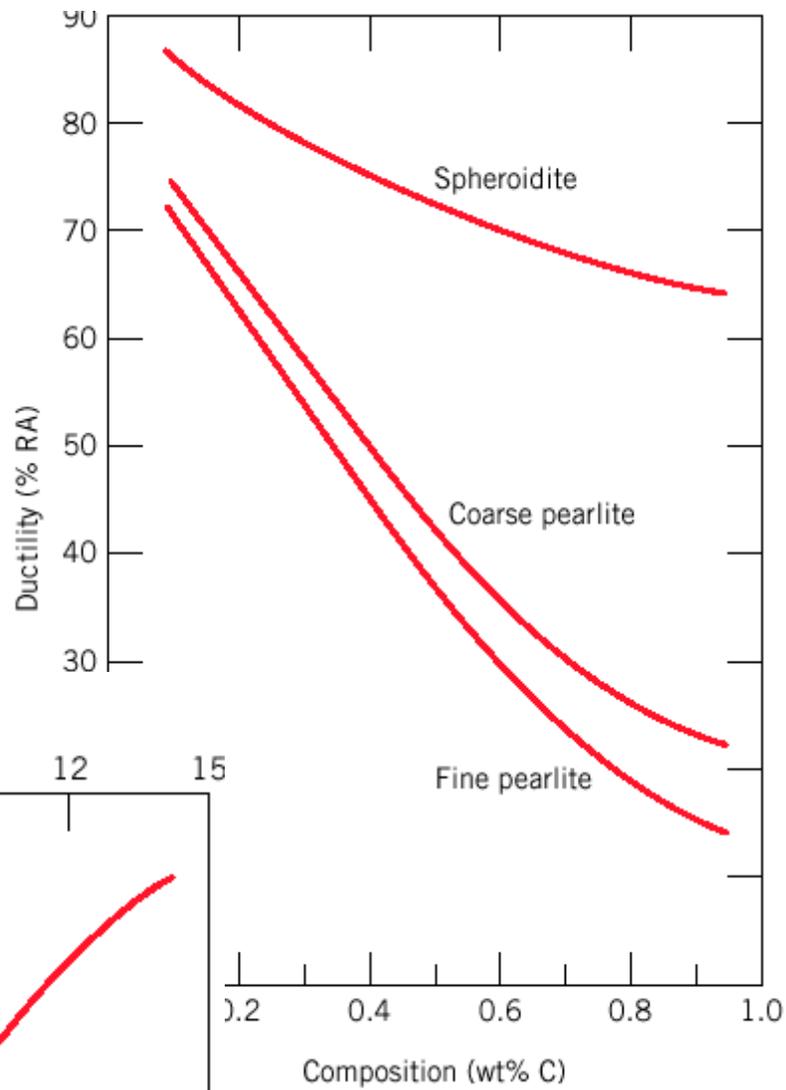

### Mechanical properties of martensite

Of the various microstructures in steel alloys

- Martensite is the hardest, strongest and the most brittle

The strength of martensite is not related to microstructure. Rather, it is related to the interstitial C atoms hindering dislocation motion (solid solution hardening, Chapter 7) and to the small number of slip systems.

# Mechanical Behavior of Fe-C Alloys (III)

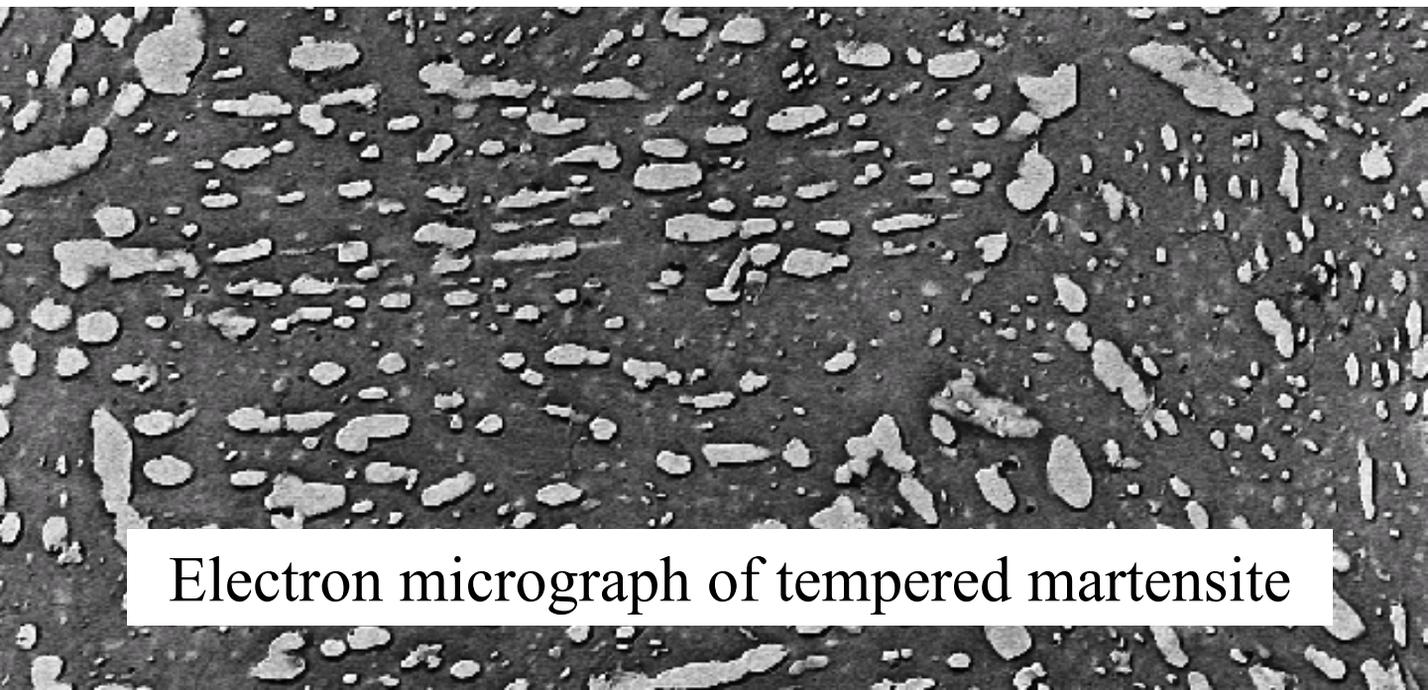

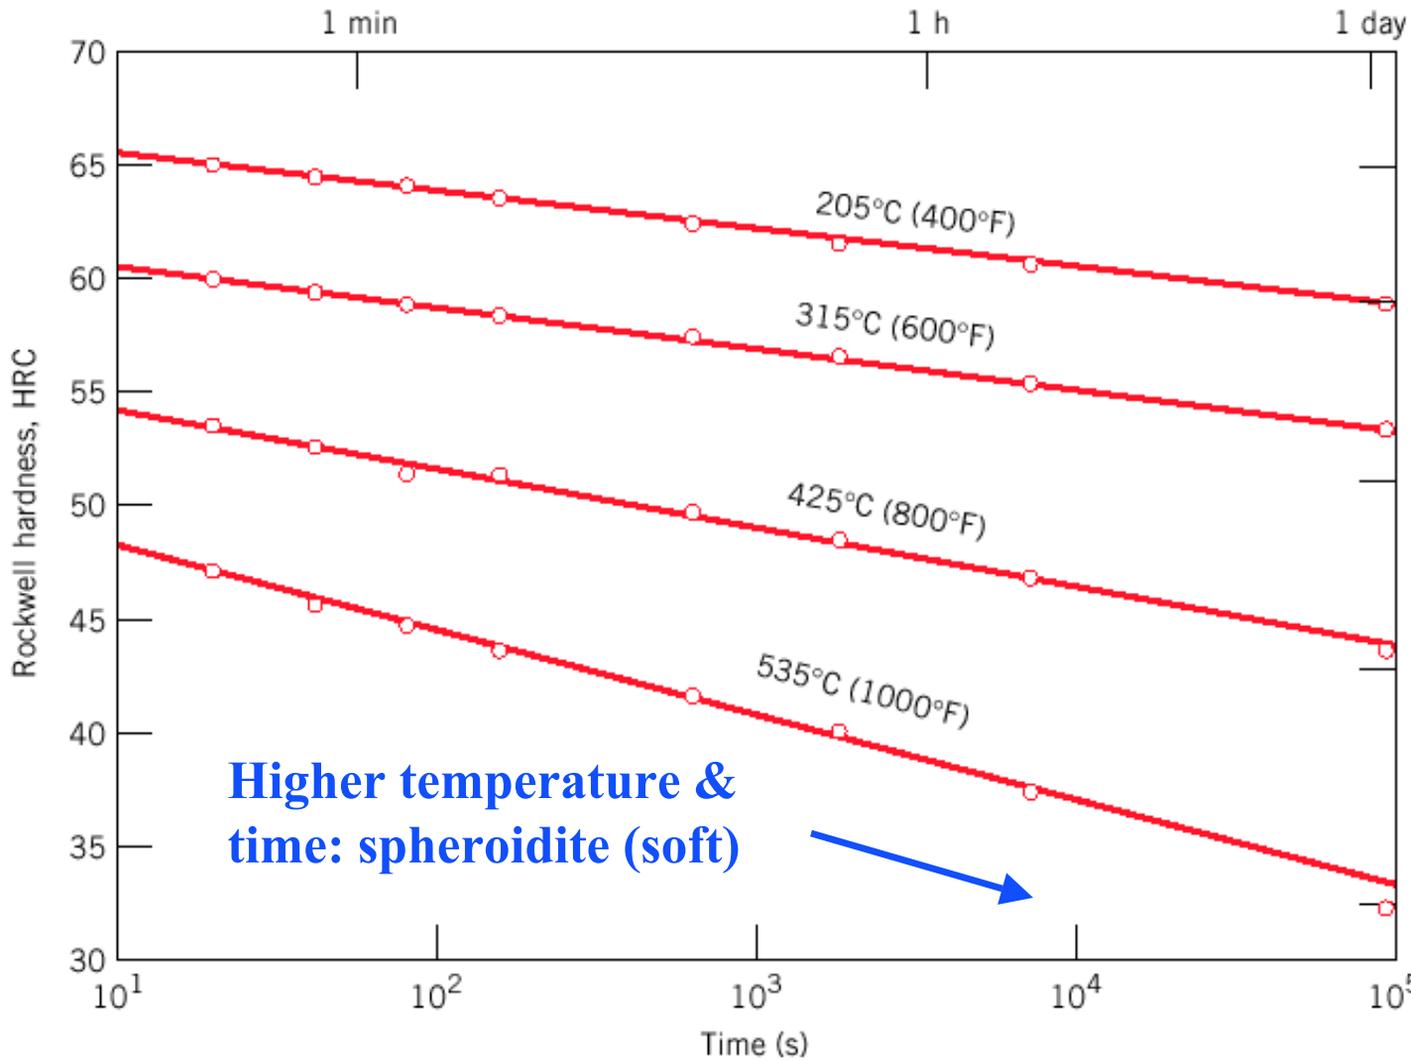

## Tempered Martensite (I)

Martensite is so brittle that it needs to be modified for practical applications. This is done by heating it to 250-650 °C for some time (tempering) which produces **tempered martensite**, an extremely fine-grained and well dispersed cementite grains in a ferrite matrix.

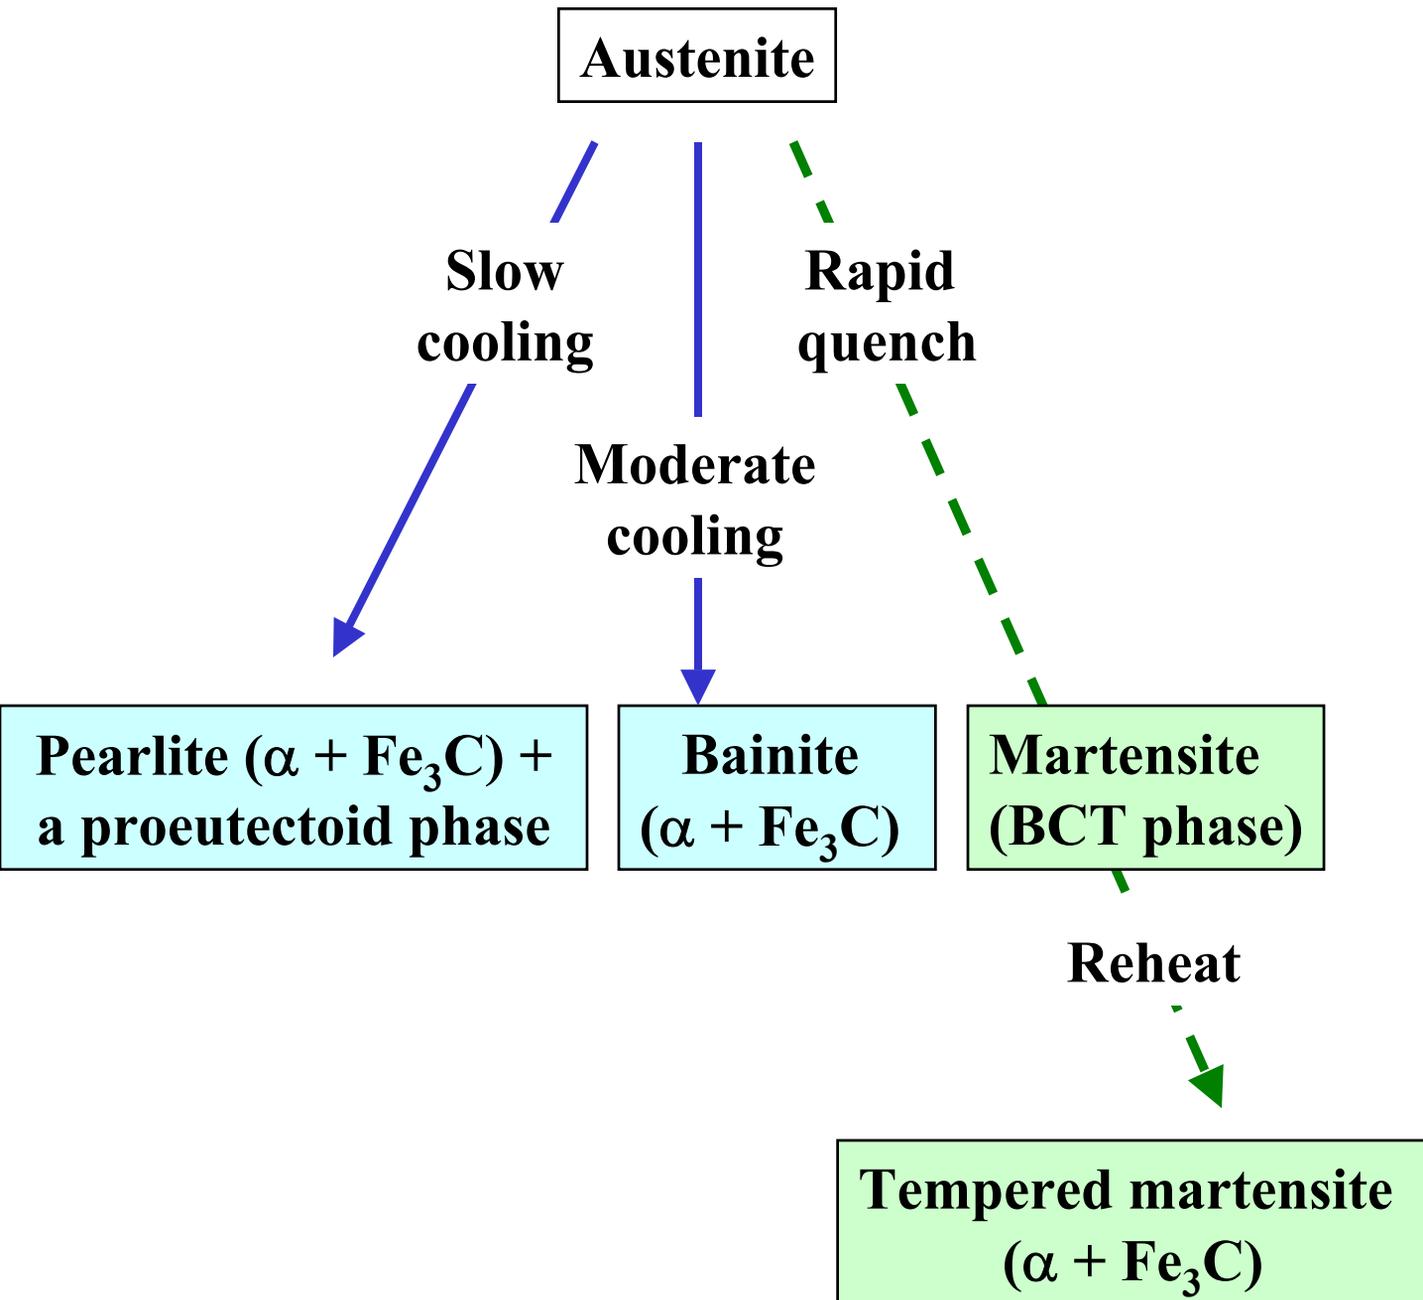

- Tempered martensite is less hard/strong as compared to regular martensite but has enhanced ductility (ferrite phase is ductile).
- Mechanical properties depend upon cementite particle size: fewer, larger particles means less boundary area and softer, more ductile material - eventual limit is spheroidite.
- Particle size increases with higher tempering temperature and/or longer time (more C diffusion) - therefore softer, more ductile material.

## Tempered Martensite (II)

Electron micrograph of tempered martensite

## Summary of austenite transformations

Solid lines are diffusional transformations, dashed is diffusionless martensitic transformation
